The bariatric surgeon must have strategies to minimise risks during and following surgery. The best way to do this is by being part of a well-established bariatric team with adequate training and throughput of surgical patients. Because of the beneficial volume–outcome effect, surgeons who carry out the greatest number of procedures have the lowest morbidity and mortality rates providing they are part of a well-established bariatric unit. Accreditation of the unit helps to make sure it adheres to high standards. It is also important for bariatric units to submit their patients to a national bariatric database for monitoring their outcomes alongside their peer group (Summary box 64.4).

EMERGING TRENDS

Typical of all surgical techniques bariatric procedures are rapidly evolving along with improvements in technology and evidence

Summary box 64.4

Minimise complications by

- Subspecialisation in bariatric surgery
- Work in a high volume accredited unit
- Compare outcomes with a national database

of effectiveness. The bariatric surgeon of the future will be doing different procedures from those of today, more likely with an array of procedures according to patient needs. The diabetic patient with a BMI between 30 and 34 kg/m² is likely to be a candidate for some form of metabolic surgery when the results from studies in these patients become available. Some of the surgical modalities used may be neuromodulation using gastric-implanted electrodes, vagal blocking using electrodes around the abdominal vagus, endoscopically placed intraluminal sleeves, endoscopic gastric restriction procedures as well as improvements in the current operations, especially involving less abdominal wall trauma by using single incision and trans-vaginal approaches. Careful evaluation will determine their place in the armamentarium for managing obesity and related metabolic conditions (Summary box 64.5).

Summary box 64.5

Experimental options

- Vagal stimulation
- Endoluminal sleeve
- Natural orifice endoscopic surgery

SUMMARY

Bariatric surgery is the only effective long-term treatment for morbid obesity. Evidence for its initial and medium-term success is overwhelming. Extension of the principles of surgery for obesity to other metabolic conditions, especially type II diabetes mellitus, will increase its usage. Newer techniques for performing this type of surgery promise to offer less complications, less invasive surgery and better outcomes.

LEARNING OBJECTIVES

To understand:

- The anatomy of the liver
- The signs of acute and chronic liver disease
- The investigation of liver disease
- The management of liver trauma, infections, cirrhosis and tumours

INTRODUCTION

The liver is the largest organ in the body, weighing 1.5 kg in the average 70-kg man. The liver parenchyma is entirely covered by a thin capsule and by visceral peritoneum on all but the posterior surface of the liver, termed the 'bare area'. The liver is divided into a large right lobe, which constitutes three-quarters of the liver parenchyma, and a smaller left lobe.

ANATOMY OF THE LIVER**Ligaments and peritoneal reflections**

The liver is fixed in the right upper quadrant by peritoneal reflections that form ligaments. On the superior surface of the left lobe is the left triangular ligament. Dividing the anterior and posterior folds of this ligament allows the left lobe to be mobilised from the diaphragm and the left lateral wall of the inferior vena cava (IVC) to be exposed. The right triangular ligament fixes the entire right lobe of the liver to the undersurface of the right hemidiaphragm. Division of this ligament allows the liver to be mobilised from under the diaphragm and rotated to the left. Another major supporting structure is the falciform ligament (remnant of the umbilical vein), which runs from the umbilicus to the liver between the right and left lobes, passing into the interlobar fissure. From the fissure, it passes anteriorly on the surface of the liver, attaching it to the posterior aspect of the anterior abdominal wall. Division of the superior leaves of the falciform ligament allows exposure of the suprahepatic IVC, lying within a thin sheath of fibrous tissue. The final peritoneal reflection is between the stomach and the liver. This lesser omentum is often thin and fragile, but contains the hilar structures in its free edge.

Liver blood supply

The blood supply to the liver is unique, 80 per cent being derived from the portal vein and 20 per cent from the hepatic artery. The arterial blood supply in most individuals is derived from the coeliac trunk of the aorta, where the hepatic artery arises along with the splenic artery. After supplying the

gastroduodenal artery, it branches at a very variable level to produce the right and left hepatic arteries. The right artery supplies the majority of the liver parenchyma and is therefore the larger of the two arteries. There are many anatomical variations, knowledge of which is essential for safe surgery on the liver. The blood supply to the right lobe of the liver may be partly or completely supplied by a right hepatic artery arising from the superior mesenteric artery. This vessel passes posterior to the uncinate process and head of the pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of the liver may be derived from the coeliac trunk via its left gastric branch. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum (Figure 65.1).

Structures in the hilum of the liver

The porta hepatis, a transverse fissure on the visceral surface of the liver, is the hilum of the liver. The hepatic artery, portal vein and bile duct are present within the free edge of the lesser omentum or the 'hepatoduodenal ligament' and together with nerves and lymphatics enter the liver at the porta hepatis. To expose these structures requires division of the overlying peritoneum followed by the division of small vessels and the lymphatic plexus. The usual anatomical relationship of these structures is for the bile duct to be within the free edge, the hepatic artery to be above and medial, and the portal vein to lie posteriorly. Within this ligament, the common hepatic duct is joined by the cystic duct at a varying level to form the common bile duct. The common hepatic artery branches at a variable level within the ligament to form two, or often three, main arterial branches to the liver. The right hepatic artery crosses the bile duct either anteriorly or posteriorly before giving rise to the cystic artery (see Figure 67.1 in Chapter 67). Multiple small hepatic arterial branches provide blood to the bile duct, principally from the right hepatic artery. The portal vein arises from the confluence of the splenic vein and the superior mesenteric vein behind the neck of the pancreas. It has some important tributaries, including the left gastric vein which joins just above the pancreas.

Figure 65.1 Hepatic angiography/conventional arterial anatomy. Arterial (a) and venous (b) phase of a selective hepatic angiogram. The hepatic artery usually arises from the coeliac trunk, along with the splenic artery, and gives rise to the gastroduodenal artery before dividing into the right and left hepatic arteries. The portal vein forms from the superior mesenteric and splenic veins, and divides into right and left branches in the hilum of the liver.

Division of structures at the hilum

At the hilum, the major structures are divided into right and left branches. The right and left hepatic ducts arise from the hepatic parenchyma and join to form the common hepatic duct. The left duct has a longer extrahepatic course of approximately 2 cm. Once within the liver parenchyma, the duct accompanies the branches of the hepatic artery and portal vein within a fibrous sheath. The portal vein often gives off two large branches to the right lobe, which are usually outside the liver for a short length, before giving a left portal vein branch that runs behind the left hepatic duct.

Venous drainage of the liver

The venous drainage of the liver is via the hepatic veins into the IVC. The vena cava lies within a groove in the posterior wall of the liver. Above the liver, it immediately penetrates

the diaphragm to join the right atrium, whereas below the liver parenchyma, there is a short length of vessel before the insertion of the renal veins. The inferior hepatic veins are short vessels that pass directly between the liver parenchyma and the anterior wall of the IVC. The major venous drainage is through three large veins that join the IVC immediately below the diaphragm. Outside the liver, these vessels are surrounded by a thin fibrous layer. The right hepatic vein can be exposed fully outside the liver, but the middle and left veins usually join within the liver parenchyma. The right kidney and adrenal gland lie immediately adjacent to the retrohepatic IVC. The right adrenal vein drains into the IVC at this level, usually via one main branch. The IVC can be mobilised fully from the retroperitoneal tissues and, in the healthy state, there are no large vessels in this tissue plane.

SEGMENTAL ANATOMY OF THE LIVER

Understanding the internal anatomy of the liver has greatly facilitated safe liver surgery. Couinaud, a French anatomist, described the liver as being divided into eight segments (Figure 65.2). Each of these segments can be considered as a functional

Figure 65.2 (a) The 'surgical' labels of the liver compared with the usual anatomical division into right and left lobes by the falciform ligament. (b) Segments of the liver (after Couinaud). IVC, inferior vena cava; LHV, left hepatic vein; LT, ligamentum teres; MHV, middle hepatic vein; RHV, right hepatic vein.

unit, with a branch of the hepatic artery, portal vein and bile duct, and drained by a branch of the hepatic vein. The overall anatomy of the liver is divided into a functional right and left 'unit' along the line between the gall bladder fossa and the middle hepatic vein (Cantlie's line). Liver segments (V–VIII), to the right of this line, are supplied by the right hepatic artery and the right branch of the portal vein, and drain bile via the right hepatic duct. To the left of this line (segments I–IV), functionally, is the left liver, which is supplied by the left branch of the hepatic artery and the left portal vein branch, and drains bile via the left hepatic duct (Summary box 65.1).

Summary box 65.1

Liver anatomy

- There are two anatomical lobes with separate blood supply, bile duct and venous drainage
- Dual blood supply (20 per cent hepatic artery and 80 per cent portal vein)
- The liver regenerates fully after partial resection
- Resection is based on anatomical lines to preserve maximal functioning liver

The hepatic lobules

The functional units within the liver segments are the liver lobules. These comprise plates of liver cells separated by the hepatic sinusoids, large, thin-walled venous channels that carry blood to the central vein, a tributary of the hepatic vein, from the portal tracts, which contain branches of the hepatic artery and portal vein. During passage through the sinusoids, the many functions of the liver take place, including bile formation, which is channelled in an opposite direction to the blood flow to drain via the bile duct tributaries within the portal tracts.

Embryology

The liver is a foregut structure and forms as a small endodermal bud early in gestation. The cell population is bipotential, and cells may develop into hepatocytes or intrahepatic ductal cells. The liver endothelium is derived from the vitelline and umbilical veins, which merge with the endodermal bud to form the liver sinusoids. The supporting connective tissue, haemopoietic cells, and Kupffer cells are derived from the mesoderm of the septum transversum which is a mass of mesenchymal connective tissue.

ACUTE AND CHRONIC LIVER DISEASE

Liver function and tests

Adequate liver function is essential to survival; humans will survive for only 24–48 hours in the anhepatic state despite full supportive therapy. The liver is central to many key metabolic pathways (Summary box 65.2).

An awareness of the currently available liver function tests and their significance is essential (Table 65.1).

Bilirubin is synthesised in the liver and excreted in bile. Increased levels may be associated with increased haemoglobin breakdown, hepatocellular dysfunction resulting in impaired bilirubin transport and excretion, or biliary obstruction. In

Summary box 65.2

Main functions of the liver

- Maintaining core body temperature
- pH balance and correction of lactic acidosis
- Synthesis of clotting factors
- Glucose metabolism, glycolysis and gluconeogenesis
- Urea formation from protein catabolism
- Bilirubin formation from haemoglobin degradation
- Drug and hormone metabolism and excretion
- Removal of gut endotoxins and foreign antigens

Table 65.1 Routinely available tests of liver function.

Test	Normal range
Bilirubin	5–17 µmol/L
Alkaline phosphatase (ALP)	35–130 IU/L
Aspartate transaminase (AST)	5–40 IU/L
Alanine transaminase (ALT)	5–40 IU/L
Gamma-glutamyl transpeptidase (GGT)	10–48 IU/L
Albumin	35–50 g/L
Prothrombin time (PT)	12–16 s

patients with known parenchymal liver disease, progressive elevation of bilirubin in the absence of a secondary complication suggests deterioration in liver function. The serum alkaline phosphatase is particularly elevated with cholestatic liver disease or biliary obstruction. The transaminase levels (aspartate transaminase (AST) and alanine transaminase (ALT)) reflect acute hepatocellular damage, as does the gamma-glutamyl transpeptidase (GGT) level, which may be used to detect the liver injury associated with acute alcohol ingestion. The synthetic functions of the liver are reflected in the ability to synthesise proteins (albumin level) and clotting factors (prothrombin time). The standard method of monitoring liver function in patients with chronic liver disease is serial measurement of bilirubin, albumin and prothrombin time.

Clinical signs of impaired liver function

These signs depend on the severity of dysfunction and whether it is acute or chronic.

Acute liver failure

Causes of acute liver failure

In the early stages, there may be no objective signs, but with severe dysfunction the onset of clinical jaundice may be associated with neurological signs of liver failure (hepatic encephalopathy), consisting of a liver flap, drowsiness, confusion and, eventually, coma (Summary box 65.3).

Treatment of acute liver failure

The overall mortality from acute liver failure is approximately 50 per cent, even with the best supportive therapy (Summary box 65.4).

Summary box 65.3**Causes of acute liver failure**

- Viral hepatitis (hepatitis A, B, C, D, E)
- Drug reactions (halothane, isoniazid–rifampicin, antidepressants, non-steroidal anti-inflammatory drugs, valproic acid)
- Paracetamol overdose
- Mushroom poisoning
- Shock and multiorgan failure
- Acute Budd–Chiari syndrome
- Wilson’s disease
- Fatty liver of pregnancy

Summary box 65.4**Supportive therapy for acute liver failure**

- Fluid balance and electrolytes
- Acid–base balance and blood glucose monitoring
- Nutrition
- Renal function (haemofiltration)
- Respiratory support (ventilation)
- Monitoring and treatment of cerebral oedema
- Treat bacterial and fungal infection

Liver transplantation is appropriate for some patients with acute liver failure (Summary box 65.5), although the short-term results are poor in comparison with liver transplantation for chronic liver disease.

Summary box 65.5**Criteria for orthotopic liver transplantation in acute liver failure**

- Paracetamol induced
 - pH <7.30 (irrespective of grade of encephalopathy) or prothrombin time (PT) >100 s + serum creatinine >300 µmol/L + grade 3 or 4 encephalopathy.
- Non-paracetamol induced (irrespective of encephalopathy) PT >100 s

or any three of the following:

- Age <10 years or >40 years
- Aetiology non-A, non-B, halothane or idiosyncratic drug reaction
- More than 7 days’ jaundice before encephalopathy
- PT >50 s
- Bilirubin >300 µmol/L

O’Grady *et al. Gastroenterology* 1989; **97**: 439–45.

Chronic liver disease

Lethargy and weakness are common features irrespective of the underlying cause. This often precedes clinical jaundice, which indicates the liver’s inability to metabolise bilirubin. The serum bilirubin level reflects the severity of the underlying liver

disease. Progressive deterioration in liver function is associated with a hyperdynamic circulation involving a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is a common feature, which may be related to underlying inflammation and cytokine release from the diseased liver or may be due to bacterial infection, to which patients with chronic liver disease are predisposed. Skin changes may be evident, including spider naevi*, cutaneous vascular abnormalities that blanch on pressure, palmar erythema and white nails (leuconychia). Endocrine abnormalities are responsible for hypogonadism and gynaecomastia. The mental derangement associated with chronic liver disease is termed ‘hepatic encephalopathy’. This is associated with memory impairment, confusion, personality changes, altered sleep patterns and slow, slurred speech. The most useful clinical sign is the flapping tremor demonstrated by asking the patient to extend his or her arms and hyperextend the wrist joint. Abdominal distension due to ascites is a common late feature. This may be suggested clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces loss of muscle bulk and wasting, and a coagulation defect is suggested by the presence of skin bruising. A patient with the typical features of end-stage chronic liver disease is shown in Figure 65.3 (Summary box 65.6).

Classifying the severity of chronic liver disease

Two prognostic models commonly used to assess the severity of chronic liver disease and perioperative risk are the Child–Turcotte–Pugh (CTP) Classification and the Model for End-Stage Liver Disease (MELD) score. The CTP classification has been modified from the original Child classification which was developed to predict mortality following shunt surgery in cirrhotic patients. The CTP classification is shown in Table 65.2. The MELD score was originally developed to predict short-term

Figure 65.3 A patient with end-stage liver cirrhosis disease, demonstrating muscle wasting and gross abdominal distension due to ascites.

Summary box 65.6**Features of chronic liver disease**

- Lethargy
- Fever
- Jaundice
- Protein catabolism (wasting)
- Coagulopathy (bruising)
- Cardiac (hyperdynamic circulation)
- Neurological (hepatic encephalopathy)
- Portal hypertension
 - Ascites
 - Oesophageal varices
 - Splenomegaly
- Cutaneous
 - Spider naevi
 - Palmar erythema

prognosis in patients undergoing transjugular intrahepatic portosystemic shunt insertion, but has now been adopted to prioritise patients awaiting liver transplantation. In the MELD model, the survival probability of patients with end-stage liver disease is computed based on the patient's international normalised ratio (INR), serum bilirubin and serum creatinine.

Table 65.2 Child–Turcotte–Pugh (CTP) classification of hepatocellular function in cirrhosis.

Points	1 point each	2 points each	3 points each
Bilirubin ($\mu\text{mol/L}$)	<34	34–50	>50
Albumin (g/L)	>35	25–35	<25
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Grade I–II	Grade III–IV
INR	<1.7	1.7–2.2	>2.2

CTP A = 5–6 points; CTP B = 7–9 points; CTP C = 10–15 points.
INR, international normalised ratio.

IMAGING THE LIVER

The major advances that have taken place over recent years in surgical approaches to the liver and the enormous improvement in the safety of liver surgery are a result of the careful individualised planning of surgery achieved through improvements in preoperative imaging. The ideal choice of imaging modality is determined by the likely liver pathology and the locally available equipment and radiological expertise (Table 65.3).

Ultrasound

This is the first-line test owing to its safety and wide availability. It is entirely operator dependent. It is useful for determining bile duct dilatation, the presence of gallstones (Figure 65.4) and the presence of liver tumours. Ultrasound can reliably differentiate between cystic and solid masses. Doppler ultrasound allows flow in the hepatic artery, portal vein and hepatic veins to be assessed. In some countries, it is used as a screening test for the

Table 65.3 Imaging the liver.

Imaging modality	Principal indication
Ultrasound	Standard first-line investigation
Spiral CT	Anatomical planning for liver surgery
MRI	Alternative to spiral CT
MRCP	First-line, non-invasive cholangiography
ERCP	Imaging the biliary tract when endoscopic intervention is anticipated (e.g. ductal stones)
PTC	Biliary tract imaging when ERCP impossible or failed
Angiography	To detect vascular involvement by tumour
Nuclear medicine	To quantify biliary excretion and tumour spread
Laparoscopy/ laparoscopic ultrasound	To detect peritoneal tumour spread and superficial liver metastases

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging; PTC, percutaneous transhepatic cholangiography.

Figure 65.4 Ultrasound scan of the upper abdomen, showing the liver on the left and a gall bladder containing multiple gallstones centrally. The stones can be seen to cast an acoustic shadow.

development of primary liver cancers in a high-risk population. Ultrasound is useful in guiding the percutaneous biopsy of a liver lesion, and aspiration of liver abscesses.

Computed tomography

Modern computed tomography (CT) technology has increased the accuracy of diagnosis and staging of liver lesions, and contrast-enhanced computed tomography is currently the most widely used and best validated modality for liver imaging. This provides fine detail of liver lesions down to less than 1 cm in diameter and gives information on their nature (Figure 65.5). Oral contrast enhancement allows visualisation of the stomach and duodenum in relation to the liver hilum. The early arterial phase of the intravenous contrast vascular enhancement is particularly useful for detecting small primary liver cancers, owing to their preferential arterial blood supply. The venous phase

Figure 65.5 Computed tomography (CT) scan of a patient with a liver tumour in the left lobe of the liver, using intravenous contrast enhancement. The vascularity of the lesion and, hence, its possible nature can be determined from the arterial (a) and venous (b) phases of the scan.

maps the branches of the portal vein within the liver and the drainage via the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas the common haemangioma characteristically shows late venous enhancement. The density of any liver lesion can be measured, which can be useful in establishing the presence of a cystic lesion. CT has high accuracy in determining the stage, and high sensitivity and specificity in determining resectability of liver tumours. Local and distant metastases can also be detected, although peritoneal metastases are often missed on CT.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) (Figure 65.6) would appear to be as effective an imaging modality as CT in the majority of patients with liver disease. It does, however, offer several advantages. First, the use of iodine-containing intravenous contrast agents is precluded in many patients because of a history of allergy. These patients should be offered MRI rather than contrast CT. Second, magnetic resonance cholangiopancreatography (MRCP) provides excellent quality, non-invasive imaging of the biliary tract, the accuracy of which is comparable to direct cholangiography by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous

Figure 65.6 The role of magnetic resonance imaging (MRI) in liver disease. MRI is increasingly used for imaging the liver. It may be used for cross-sectional imaging for staging liver cancers (MRI) (a), for non-invasive cholangiography to demonstrate a hilar stricture (magnetic resonance cholangiopancreatography, MRCP) (b), or for the non-invasive assessment of blood vessels (magnetic resonance angiography, MRA).

transhepatic cholangiography (PTC). Complementary to CT, MRI and MRCP are the best imaging modalities for suspected hilar cholangiocarcinoma. It is useful for diagnostic questions when ERCP has failed or is impossible due to previous surgery. Magnetic resonance angiography (MRA) similarly provides high-quality images of the hepatic artery and portal vein, without the need for arterial cannulation. It is used as an alternative to selective hepatic angiography for diagnosis. It is particularly useful in patients with chronic liver disease and coagulopathy in whom the patency of the portal vein and its branches is in question.

Endoscopic retrograde cholangiopancreatography

ERCP (Figure 65.7a) is performed in patients with obstructive jaundice when an endoscopic intervention is anticipated based on imaging (endoscopic removal of common bile duct

Figure 65.7 (a) Endoscopic retrograde cholangiopancreatography demonstrating the biliary tract with multiple stones in the distal common bile duct. (b) Percutaneous transhepatic cholangiography. Some contrast has extravasated at the site of hepatic puncture of the percutaneously placed needle, but the biliary tract is clearly demonstrated and shows the multiple strictures typical of primary sclerosing cholangitis.

(CBD) stones, biliary drainage in a septic patient or insertion of a biliary tract stent). A preoperative check of coagulation is essential, along with prophylactic antibiotics and an explanation of the main complications, which include pancreatitis, cholangitis and bleeding or perforation of the duodenum related to sphincterotomy.

Percutaneous transhepatic cholangiography

PTC is indicated where endoscopic cholangiography has failed or is impossible, e.g. in patients with previous pancreato-

duodenectomy or Pólya gastrectomy. It is often required in patients with hilar bile duct tumours to guide external drainage of the obstructed bile ducts to relieve jaundice, evaluate resectability and to direct stent insertion (Figure 65.7b).

Angiography

Selective visceral angiography (see Figure 65.1) can provide accurate assessment of vascular involvement by tumour, but the technique is invasive. CT and MRA have evolved and their diagnostic accuracy is comparable to conventional angiography which is nowadays mostly employed for therapeutic intervention only. Therapeutic interventions include the occlusion of arteriovenous malformations, the embolisation of bleeding sites in the liver and the treatment of liver tumours (transarterial embolisation, TAE).

Nuclear medicine scanning

Radioisotope scanning can provide important diagnostic information. HIDA is a technetium-99m (^{99m}Tc)-labelled radio-nuclide that is administered intravenously, removed from the circulation by the liver, processed by hepatocytes and excreted in the bile. Imaging under a gamma camera allows its uptake and excretion to be monitored in real time. This is a useful non-invasive test when there is suspicion of bile leak.

^{18}F -2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET) depends on the avid uptake of glucose by cancerous tissue in comparison with benign or inflammatory tissue. Deoxyglucose is labelled with the positron emitter fluorine-18 (^{18}F FDG), and this is administered to the patient prior to imaging by positron emission tomography (PET). A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (Figure 65.8). PET or

Figure 65.8 Whole-body positron emission tomography in a patient with colorectal metastases showing widespread areas of ^{18}F -2-fluoro-2-deoxy-D-glucose uptake, indicating the sites of metastatic disease.

integrated PET-CT can be useful in the diagnosis of regional lymph node metastases and distant metastases particularly when CT and MRI findings are equivocal.

Laparoscopy

Laparoscopy is useful for the staging of hepatopancreatobiliary cancers particularly primary liver and biliary tract cancers. Lesions overlooked by conventional imaging are mainly peritoneal metastases and superficial liver tumours. These lesions can be detected at laparoscopy, thus avoiding an unnecessary laparotomy. A liver biopsy to confirm or exclude chronic liver disease can also be performed during laparoscopy.

LIVER TRAUMA

General

The liver is the second most common organ injured in abdominal trauma.

Liver trauma can be divided into blunt and penetrating injuries. Blunt injury produces contusion, laceration and avulsion injuries to the liver, often in association with splenic, mesenteric or renal injury. Penetrating injuries, such as stab and gunshot wounds, are often associated with chest or pericardial involvement (Summary box 65.7). Blunt injuries are more common and have a higher mortality than penetrating injuries.

Summary box 65.7

Management of liver trauma

- Remember associated injuries
- At-risk groups
 - Stabbing/gunshot in lower chest or upper abdomen
 - Crush injury with multiple rib fractures
- Resuscitate
 - Airway
 - Breathing
 - Circulation
- Assessment of injury
 - CT chest and abdomen with contrast
 - Laparotomy if haemodynamically unstable
- Treatment
 - Correct coagulopathy
 - Suture lacerations
 - Resect if major vascular injury
 - Packing if diffuse parenchymal injury

Diagnosis of liver injury

The liver is an extremely well-vascularised organ, and blood loss is therefore the major early complication of liver injuries. Clinical suspicion of a possible liver injury is essential, as a laparotomy by an inexperienced surgeon with inadequate preparation preoperatively is doomed to failure. All lower chest and upper abdominal stab wounds should be suspect, especially if considerable blood volume replacement has been required. Similarly, severe crushing injuries to the lower chest or upper abdomen often combine rib fractures, haemothorax and damage to the spleen and/or liver. Focused assessment sonography

in trauma (FAST) performed in the emergency room by an experienced operator can reliably diagnose free intraperitoneal fluid. Patients with free intraperitoneal fluid on FAST and haemodynamic instability, and patients with a penetrating wound will require a laparotomy and/or thoracotomy once active resuscitation is under way. Owing to the opportunity for massive ongoing blood loss and the rapid development of a coagulopathy, the patient should be directly transferred to the operating theatre while blood products are obtained and volume replacement is taking place. Patients who are haemodynamically stable should have a contrast-enhanced CT scan of the chest and abdomen as the next step. This will demonstrate evidence of parenchymal damage to the liver or spleen, as well as associated traumatic injuries to their feeding vessels. Free fluid can also be clearly established. The chest scan will help to exclude injuries to the great vessels and demonstrate damage to the lung parenchyma. Additional investigations that may be of value include diagnostic peritoneal lavage, which can confirm the presence of haemoperitoneum, but this is rarely performed nowadays due to increased use of FAST and CT.

Initial management of liver injuries

Penetrating

The initial management is maintenance of airway patency, breathing and circulation (ABC) following the principles of advanced trauma life support (ATLS). Peripheral venous access is gained with two large-bore cannulae and blood sent for cross-match of ten units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with colloid or O-negative blood if necessary. Arterial blood gases should be obtained and the patient intubated and ventilated if the gas exchange is inadequate. Intercostal chest drains should be inserted if associated pneumothorax or haemothorax is suspected. Once initial resuscitation has commenced, the patient should be transferred to the operating theatre, with further resuscitation performed on the operating table. The necessity for fresh-frozen plasma and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives, as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and factors should be given empirically, aided by the results of thromboelastography (TEG), if available (Figure 65.9). A contrast CT prior to laparotomy should be considered if the patient is haemodynamically stable.

Blunt trauma

With blunt injuries, the initial plan for resuscitation and management is as outlined above for penetrating injuries. Patients who are haemodynamically unstable will require an immediate laparotomy. For the patient who is haemodynamically stable, imaging by CT should be performed to further evaluate the nature of the injury. Most patients with blunt liver injury who are haemodynamically stable can be managed conservatively. The indication for discontinuing conservative treatment for blunt liver trauma would be development of haemodynamic instability, evidence of ongoing blood loss despite correction of any underlying coagulopathy and the development of signs of generalised peritonitis. Interventional radiology has an

Figure 65.9 Thromboelastography (TEG). This dynamic form of assessing the coagulation status is being used increasingly for intraoperative monitoring. The shape of the TEG trace defines the nature of the underlying coagulation deficiency as shown. A, normal; B, delayed clot formation; C, reduced clot strength; D, clot lysis; E, hypercoagulable.

important role in management of liver trauma and embolisation to control hepatic artery bleeding is safe and effective in a stable patient with no evidence of hollow viscus perforation.

The surgical approach to liver trauma

Good access is vital. A 'rooftop' incision with midline extension to the xiphisternum and retraction of the costal margins gives excellent access to the liver and spleen. If the laparotomy has been started through a midline incision, a transverse lateral extension to the right can be added to improve access to the liver. Compression of the liver with packs and correction of coagulopathy, if present, will control most of the active bleeding. If bleeding persists, further control can be achieved by vascular inflow occlusion by placing an atraumatic clamp across the foramen of Winslow (the Pringle manoeuvre). A stab incision in the liver can be sutured with a fine absorbable monofilament suture. Lacerations to the hepatic artery should be identified and repaired with 6/0 Prolene suture. If unavoidable, the hepatic artery may be ligated, although parenchymal necrosis and abscess formation will result in some individuals. Portal vein injuries should be repaired with 5/0 Prolene. Inflow occlusion facilitates suturing of lacerations and vessels.

If bleeding persists despite inflow occlusion, consider major hepatic vein or IVC injuries, and also look for aberrant arteries to the liver. Deceleration injuries often produce lacerations of the liver parenchyma adjacent to the anchoring ligaments of the liver. These may be amenable to suture with an absorbable monofilament suture. Again, inflow occlusion may facilitate this suturing and, if necessary, the sutures can be buttressed to prevent them cutting through the liver parenchyma. With more severe deceleration injuries, a portion of the liver may be avulsed. These injuries are more complex as they are associated with a devitalised portion of the liver and, often, major injuries to the hepatic veins and IVC. Diffuse parenchymal injuries

should be treated by packing the liver to produce haemostasis. This is effective for the majority of liver injuries if the liver is packed against the natural contour of the diaphragm by packing from below. Large abdominal packs should be used to ease their removal, and the abdomen closed to facilitate compression of the parenchyma. Care should be taken to avoid overzealous packing, as this may produce pressure necrosis of the liver parenchyma or abdominal compartment syndrome.

Crush injuries to the liver often result in large parenchymal haematomas and diffuse capsular lacerations. Suturing is usually ineffective, and perihepatic packing which involves placing packs above, behind and below the liver, is the most useful method of providing haemostasis. Necrotic tissue should be removed, but poorly perfused, though viable, liver left *in situ*. If packing is necessary, the patient should have the packs removed after 48 hours, and usually no further surgical intervention is required. Antibiotic cover is advisable, and full reversal of any coagulopathy is essential. If a major liver vascular injury is suspected at the time of the initial laparotomy, then referral to a specialist centre should be considered. A common surgical approach in these circumstances would be to place the patient on venovenous bypass using cannulae in the femoral vein via a long saphenous cut-down with the blood returned, using a roller pump, to the superior vena cava (SVC) via an internal jugular line. Venovenous bypass allows the IVC to be safely clamped to facilitate caval or hepatic vein repair. A rapid infuser blood transfusion machine facilitates the delivery of large volumes of blood instantaneously. Once prepared, the patient is relaparotomised via the rooftop incision with a midline extension to the xiphisternum. The liver is mobilised by division of the supporting ligaments, and complete vascular isolation of the liver is achieved by occluding the hilar inflow and the IVC above the renal veins and at the level of the diaphragm with atraumatic vascular clamps. Venous return is provided by the venovenous bypass. Warm ischaemia of the liver is tolerated for up to 45 minutes, allowing sufficient time in a blood-free field for repair of injuries to the IVC or hepatic veins.

Other complications of liver trauma

A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia, especially after penetrating trauma. Treatment is with systemic antibiotics and aspiration under ultrasound guidance once the necrotic tissue has liquefied. Bile collections require aspiration under ultrasound guidance or percutaneous insertion of a pigtail drain. The site of origin of a biliary fistula should be determined by endoscopic or percutaneous cholangiography, and biliary decompression achieved by nasobiliary or percutaneous transhepatic drainage or endoprosthesis insertion. If this fails to control the fistula, the affected portion of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous or arterio-biliary fistulae (Figure 65.10). These are best treated nonsurgically by a specialist hepatobiliary interventional radiologist. The feeding vessel can be embolised transarterially.

Hepatic failure may occur following extensive liver trauma. This will usually reverse with conservative supportive treatment if the blood supply and biliary drainage of the liver are intact (Summary box 65.8).

James Hogarth Pringle, 1863–1941, surgeon, The Royal Infirmary, Glasgow, UK. Born in Australia and trained in Edinburgh, he was a strong supporter of women in medicine; he performed the first successful autologous vein graft in the UK and the first excision and block dissection for malignant melanoma. He and his father, George Hogarth Pringle (1830–1872, who practised in Australia), formed a famous team of surgical innovators.

Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.

Summary box 65.8

Other complications of liver trauma

- Intrahepatic haematoma
- Liver abscess
- Bile collection
- Biliary fistula
- Hepatic artery aneurysm
- Arteriovenous fistula
- Arteriovenous fistula
- Liver failure

Long-term outcome of liver trauma

The capacity of the liver to recover from extensive trauma is remarkable, and parenchymal regeneration occurs rapidly. Late complications are rare, but the development of biliary tract strictures many years after recovery from liver trauma has been reported. The treatment depends on the mode of presentation and the extent and site of stricturing. A segmental or lobar stricture, associated with atrophy of the corresponding area of liver parenchyma and compensatory hypertrophy of the other liver lobe, may be treated expectantly. A dominant extrahepatic bile duct stricture associated with obstructive jaundice may be treated initially with endobiliary balloon dilatation or stenting, but will usually require surgical correction using a Roux-en-Y hepatochojunostomy.

PORTAL HYPERTENSION

An elevation in portal pressure is most commonly found in the presence of liver cirrhosis, although it may be present in patients with extrahepatic portal vein occlusion, intrahepatic

veno-occlusive disease or occlusion of the main hepatic veins (Budd–Chiari syndrome (BCS)). As portal hypertension per se produces no symptoms, it is usually diagnosed following presentation with decompensated chronic liver disease and encephalopathy, ascites or variceal bleeding.

Management of bleeding varices

General resuscitation

Varices usually present with the acute onset of a large-volume haematemesis, the lower oesophagus being the most common site for variceal bleeding. The diagnosis may be suspected if the patient is known to have liver cirrhosis, but it needs to be confirmed following initial resuscitation of the patient. Variceal haemorrhage is a medical emergency. Patients with massive haemorrhage should be admitted to the intensive treatment unit (ITU). Venous access should be obtained through two large bore peripheral cannulae. Colloids should be administered while adequate blood is obtained (initially ten units). Liver function tests will reveal underlying liver disease, and a coagulation profile will reveal any underlying coagulopathy. Blood volume should be replaced with colloids, plasma expanders and blood transfusions. Hypervolaemia should be avoided since this may increase portal pressure and exacerbate the bleeding. Vitamin K is administered (10 mg intravenously (i.v.)), but correction of a coagulopathy will require the administration of fresh-frozen plasma (FFP). An associated thrombocytopenia is usually secondary to hypersplenism due to cirrhosis and is treated if the platelet count falls below $50 \times 10^9/L$. Treatment with a splanchnic vasoconstrictor should be started. Administration of a prophylactic antibiotic is recommended to prevent or treat associated bacterial infection. As soon as the patient is haemodynamically stabilised an upper gastrointestinal endoscopy should be performed to establish the diagnosis because 50 per cent of patients with portal hypertension will have a non-variceal source of bleeding. Variceal bleeding is often associated with hepatic encephalopathy and, in these circumstances and when bleeding is severe, endotracheal intubation will be required for endoscopy. Bronchial aspiration is a frequent complication of variceal bleeding (Summary box 65.9).

Summary box 65.9

Management of bleeding oesophageal varices

- Blood transfusion
- Correct coagulopathy
- Oesophageal balloon tamponade (Sengstaken–Blakemore tube)
- Drug therapy (vasopressin/octreotide)
- Endoscopic sclerotherapy or banding
- Assess portal vein patency (Doppler ultrasound or CT)
- Transjugular intrahepatic portosystemic stent shunts (TIPSS)
- Surgery
 - Portosystemic shunts
 - Oesophageal transection
 - Splenectomy and gastric devascularisation

If the rate of blood loss prohibits endoscopic evaluation, a Sengstaken–Blakemore tube may be inserted to provide temporary haemostasis. This is shown diagrammatically in Figure 65.11. Once inserted, the gastric balloon is inflated with 300 mL

Figure 65.11 Oesophageal balloon tamponade.

of air and retracted to the gastric fundus, where the varices at the oesophagogastric junction are tamponaded by the subsequent inflation of the oesophageal balloon to a pressure of 40 mmHg. The two remaining channels allow gastric and oesophageal aspiration. An x-ray is used to confirm the position of the tube. The balloons should be temporarily deflated after 12 hours to prevent pressure necrosis of the oesophagus. Aspiration pneumonia and oesophageal ulceration are other complications. Balloon tamponade is very effective in stopping bleeding and once the patient is stabilised, a more definitive treatment can be carried out.

Drug treatment for variceal bleeding

Splanchnic vasoconstrictors reduce portal flow and pressure and should be started early in the treatment of variceal haemorrhage. Vasopressin is a potent vasoconstrictor and has been the most extensively used drug for the initial control of variceal haemorrhage, but it can cause myocardial ischaemia, arrhythmias, mesenteric and limb ischaemia. Terlipressin, somatostatin and octreotide are safer than vasopressin and equally effective.

Endoscopic treatment of varices

Treatment with a vasoconstrictor (see above) combined with endoscopic therapy is the standard medical treatment for acute variceal bleeding. The two most commonly used endoscopic techniques are endoscopic band ligation which involves placing a constricting rubber band at the base of the varix, and endoscopic sclerotherapy which involves injection of a sclerosant, such as polidocanol (1–3 per cent) or ethanolamine (5 per cent), into or around the varix. Although both are effective in controlling the bleed, banding is significantly better in preventing rebleeding and is the preferred option. The majority of variceal bleeds will respond to a single course.

Transjugular intrahepatic portosystemic stent shunts

The emergency management of variceal haemorrhage has been revolutionised by the introduction of transjugular intrahepatic portosystemic stent shunts (TIPSS) in 1988. Over a short period, it has become the main treatment of variceal haemorrhage that has not responded to drug treatment and endoscopic therapy. The shunts are inserted under local anaesthetic, analgesia and sedation using fluoroscopic guidance and ultrasonography. Via the internal jugular vein and SVC, a guidewire is inserted into a hepatic vein and through the hepatic parenchyma into a branch of the portal vein. The track through the parenchyma is then dilated with a balloon catheter to allow insertion of a metallic stent, which is expanded once a satisfactory position is achieved (Figure 65.12) to form a channel between systemic and portal venous systems. A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication of this technique is perforation of the liver capsule, which can be associated with fatal intraperitoneal haemorrhage. TIPSS occlusion may result in further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. Post-shunt encephalopathy is the confusional state caused by the portal blood bypassing the detoxification of the liver. It occurs in about 40 per cent of patients, a similar incidence to that found after surgical shunts. If severe, the lumen of the TIPSS can be reduced by insertion of a smaller stent. The

Figure 65.12 A check angiogram following insertion of a transjugular intrahepatic portosystemic stent shunt (open arrow). Injection of contrast into the portal vein flows through the metallic stent and outlines the right hepatic vein. Pressure measurements are taken from within the portal vein before and after insertion. Solid arrows indicate coils placed at the site of previous embolisation.

main contraindication to TIPSS is portal vein occlusion. The main long-term complication of TIPSS is stenosis of the shunt, which is common (approximately 50 per cent at one year) and may present as further variceal haemorrhage.

Surgical shunts for variceal haemorrhage

The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical shunts. It is rarely considered for the acute management of variceal haemorrhage, as the morbidity and mortality in these circumstances are high. The main current indication for a surgical shunt is a patient with Child's grade A cirrhosis, in whom the initial bleed has been controlled by sclerotherapy. Long-term β -blocker therapy and chronic sclerotherapy or banding are the main alternatives.

Surgical shunts are an effective method of preventing rebleeding from oesophageal or gastric varices, as they reduce the pressure in the portal circulation by diverting the blood into the low-pressure systemic circulation. Shunts may be divided into selective (e.g. splenorenal) and non-selective (e.g. portocaval), the former attempting to preserve blood flow to the liver while decompressing the left side of the portal circulation responsible for giving rise to the oesophageal and gastric varices. Selective shunts may be associated with a lower incidence of portal systemic encephalopathy (PSE), a confusional state commonly found in patients with chronic liver disease who have undergone radiological or surgical portosystemic shunts. The different types of surgical shunt are shown in Figure 65.13. There is no evidence that prophylactic shunting is beneficial in patients with varices that have not bled.

Oesophageal stapled transection

This technique for the management of bleeding oesophageal varices uses the circular stapling device for stapling and resecting a doughnut ring of the lower oesophagus. As with surgical shunts in the acute situation, it was associated with a high

perioperative mortality and has been largely abandoned in centres where TIPSS is available.

Management of recurrent variceal bleeds secondary to splenic or portal vein thrombosis

Treatment is by splenectomy and gastro-oesophageal devascularisation, in which the blood supply to the greater and lesser curve of the stomach and lower oesophagus is divided. Splenic vein thrombosis may be seen secondary to chronic pancreatitis, and portal vein thrombosis is a common late complication of liver cirrhosis.

Variceal bleeding and orthotopic liver transplantation

Liver transplantation is the only therapy which will treat portal hypertension and the underlying liver disease. The management of variceal bleeding should always take into account the possibility of liver transplantation when this is available. Previous surgical shunts greatly increase the morbidity associated with orthotopic liver transplantation. TIPSS would be the preferred management for bleeds resistant to sclerotherapy, as long as placement is optimal.

Ascites

The accumulation of free peritoneal fluid is a common feature of advanced liver disease independent of the aetiology. The fluid accumulation is usually associated with abdominal discomfort and a dragging sensation. Development is usually insidious. The aetiology of the ascites must be established (Summary box 65.10).

Imaging by CT will confirm the ascites and demonstrate the irregular and shrunken nature of a cirrhotic liver and associated splenomegaly. Intravenous contrast enhancement will allow abdominal varices to be demonstrated and assess patency of the portal vein, as portal vein thrombosis is a common predisposing

Figure 65.13 (a–d) Surgical shunts. Surgical shunts for portal hypertension involve shunting portal blood into the systemic veins. This commonly involves a side-to-side portocaval anastomosis (a) or end-to-side portocaval (b), mesocaval (c) or splenorenal (d) anastomoses.

Summary box 65.10**Determining the cause of ascites**

- Imaging (ultrasound or CT)
 - Irregular cirrhotic liver
 - Portal vein patency
 - Splenomegaly of cirrhosis
- Aspiration
 - Culture and microscopy
 - Protein content
 - Cytology
 - Amylase level

factor to the development of ascites in chronic liver disease. In patients without evidence of liver disease, malignancy is a common cause, and the primary site may also be established on CT. Aspiration of the peritoneal fluid allows the measurement of protein content to determine whether the fluid is an exudate or transudate, and an amylase estimation to exclude pancreatic ascites. Cytology will determine the presence of cancerous cells, and both microscopy and culture will exclude primary bacterial peritonitis and tuberculous peritonitis.

Treatment of ascites in chronic liver disease

The initial treatment is to restrict additional salt intake and commence diuretics using either spironolactone or furosemide. This should be combined with advice on avoiding any precipitating factors for impaired liver function, such as alcohol intake in patients with alcoholic cirrhosis. Patients on diuretics should be monitored for the development of hyponatraemia and hypokalaemia (Summary box 65.11).

Summary box 65.11**Treatment of ascites in chronic liver disease**

- Salt restriction
- Diuretics
- Abdominal paracentesis
- Peritoneovenous shunting
- Transjugular intrahepatic portosystemic stent shunts (TIPSS)
- Liver transplantation

Abdominal paracentesis

Patients who fail to respond to diuretic treatment may require repeated percutaneous aspiration of large volume of the ascites (abdominal paracentesis), combined with volume replacement using salt-poor or standard human albumin solution, dependent on the serum sodium level. Paracentesis provides only short-term symptomatic relief.

Peritoneovenous shunting

The LeVeen shunt is designed for the relief of ascites due to chronic liver disease. One end of the silastic tube is inserted into the ascites within the peritoneal cavity and the other end is tunnelled subcutaneously to the neck, where it is inserted under direct vision into the internal jugular vein and fed into the

SVC. Owing to a one-way valve within the tubing, peritoneal fluid is drawn from the abdomen and drained to the circulation due to the lower pressure in the SVC in comparison with the abdomen during the respiratory cycle. Complications include occlusion, displacement, infection and disseminated intravascular coagulation. In an attempt to prevent the high occlusion rate, a further development was the insertion of a chamber placed over the costal margin to allow digital pressure and evacuation of any debris within the peritoneovenous shunt (Denver shunt). Peritoneovenous shunts are rarely performed nowadays.

TIPSS for ascites

The use of TIPSS for ascites is for symptomatic relief. In patients with intractable ascites, TIPSS is a good alternative to repeated paracentesis, but post-stent encephalopathy is common (about 40 per cent), and the majority of stents will stenose on follow up (approximately 50 per cent by one year).

Liver transplantation for ascites

Diuretic-resistant ascites is an indication for liver transplantation if associated with deterioration in liver function (rising bilirubin, dropping albumin, prolonged prothrombin time). The patient's age, underlying aetiology of liver disease and associated medical problems will be the major factors determining suitability for liver transplantation. In those considered inappropriate for liver transplantation, management is aimed at symptomatic control of ascites.

CHRONIC LIVER CONDITIONS

There are several chronic liver conditions, which, although rare, are important to recognise because they require a specific plan for investigation and treatment, and may present mimicking a more common clinical condition (Table 65.4).

Table 65.4 Important chronic liver conditions.

Condition	Common presentations
Budd–Chiari syndrome	Ascites
Primary sclerosing cholangitis (PSC)	Abnormal LFTs or jaundice
Primary biliary cirrhosis (PBC)	Malaise, lethargy, itching, abnormal LFTs
Caroli's disease	Abdominal pain, sepsis
Simple liver cysts	Coincidental finding, pain
Polycystic liver disease	Hepatomegaly, pain

LFTs, liver function tests.

Budd–Chiari syndrome

This is a condition principally affecting young females, in which the venous drainage of the liver is occluded by hepatic venous thrombosis or obstruction from a venous web. As a result of venous outflow obstruction, the liver becomes acutely congested, with the development of impaired liver function and, subsequently, portal hypertension, ascites and oesophageal varices. In an acute thrombosis, the patient may rapidly progress

to fulminant liver failure but, in the majority of cases, abdominal discomfort and ascites are the main presenting features. If chronic, the liver progresses to established cirrhosis. The cause of the venous thrombosis needs to be established, and an underlying myeloproliferative disorder or procoagulant state is commonly found, such as anti-thrombin 3, protein C or protein S deficiency. The diagnosis is commonly suspected in a patient presenting with ascites, in whom a CT scan shows a large congested liver (early stage, Figure 65.14) or a small cirrhotic liver in which there is gross enlargement of segment I (the caudate lobe). This feature results from preservation and hypertrophy of the segment with direct venous drainage to the IVC in the face of atrophy of the rest of the liver due to venous obstruction (Figure 65.15). IVC compression or occlusion from the segment I hypertrophy is also a common feature, as is thrombosis of the portal vein. Confirmation of the suspected diagnosis

Figure 65.14 Computed tomography scan in early Budd-Chiari syndrome.

Figure 65.15 Segment I hypertrophy with Budd-Chiari syndrome.

is by hepatic venography via a transjugular approach, which demonstrates occlusion of the hepatic veins and may allow a transjugular biopsy.

Treatment of BCS must be tailored to the individual patient and, in particular, to the stage of disease at presentation. Patients presenting in fulminant liver failure should be considered for liver transplantation, as should those with established cirrhosis and the complications of portal hypertension. Those in whom cirrhosis is not established may be considered for portosystemic shunting by TIPSS, portocaval shunt or mesoatrial shunting. IVC compression may be relieved by the insertion of a retro-hepatic expandable metallic stent. If the BCS is treated satisfactorily, the prognosis of this patient group is largely dependent on the underlying aetiology and whether this is amenable to treatment. Patients are usually left on lifelong anticoagulation with warfarin.

Primary sclerosing cholangitis

This condition often presents in young adults with mild non-specific symptoms, and biliary disease is suggested by the finding of abnormal liver function tests. Rarely, the first presentation is with jaundice due to biliary obstruction. The disease process results in progressive fibrous stricturing and obliteration of both the intrahepatic and the extrahepatic bile ducts. Although the aetiology is unknown, a genetic predisposition is likely owing to its association with ulcerative colitis (UC). In patients with primary sclerosing cholangitis (PSC) and UC, the condition usually progresses even if the diseased colon is removed. The diagnosis is principally based on the findings at cholangiography, in which irregular, narrowed bile ducts are demonstrated in both the intrahepatic and the extrahepatic biliary tree (Figure 65.16). If the radiological appearances are equivocal, a liver biopsy is required to demonstrate the fibrous obliteration of the biliary tracts. There is no specific treatment that can reverse the ductal changes, and the patients usually slowly progress to progressive cholestasis and death from liver failure. There is a strong predisposition to cholangiocarcinoma (CCA), and this should be considered in any patient with PSC in whom a new or dominant stricture is demonstrated on cholangiography.

Diagnosis of CCA in PSC is greatly facilitated by biliary brush cytology, as imaging rarely shows evidence of a mass lesion even in patients with advanced CCA. Further, imaging cannot reliably differentiate between inflammatory and malignant biliary strictures. Serum CA 19-9 level may be increased but the sensitivity of CA 19-9 in detecting CCA in PSC is approximately 60 per cent. Patients with good liver function, no dominant strictures and negative biliary cytology may simply be monitored for disease progression. The only useful treatment modality is liver transplantation, which is associated with excellent results if carried out before bile duct cancer has developed. Temporary relief of obstructive jaundice due to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis from the introduction of bacteria to the biliary tract.

Primary biliary cirrhosis

As with PSC, the presentation of patients with primary biliary cirrhosis (PBC) is often hidden, with general malaise, lethargy and pruritus prior to the development of clinical jaundice or the finding of abnormal liver function tests. The condition is largely confined to females. Diagnosis is suggested by the finding

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK, described this syndrome in 1845.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of the First World War in 1918) gave his account of this condition in 1898.

Figure 65.16 Primary sclerosing cholangitis (PSC). Percutaneous cholangiography showing the characteristic extensive bile duct strictures and dilations associated with PSC.

of circulating anti-smooth muscle antibodies and, if necessary, is confirmed by liver biopsy. The condition is slowly progressive, with deterioration in liver function resulting in lethargy and malaise. It may be complicated by the development of portal hypertension and the secondary complications of ascites and variceal bleeding. The mainstay of treatment is liver transplantation, which should be considered when the patient's general condition starts to deteriorate with inability to lead a normal lifestyle.

Caroli's disease

This is congenital dilatation of the intrahepatic biliary tree, which is often complicated by the presence of intrahepatic stone formation. Presentation may be with abdominal pain or sepsis. Imaging is usually diagnostic, with the finding on ultrasound or CT of intrahepatic biliary lakes containing stones. Biliary stasis and stone formation combine to predispose to biliary sepsis, which may be life-threatening. Another well-recognised complication is the development of carcinoma. No specific treatment is available. Acute infective episodes are treated with antibiotics. Obstructed and septic bile ducts may be drained either radiologically or surgically. Malignant change within the ductal system results in cholangiocarcinoma, which may be amenable to resection. Segmental involvement of the liver by Caroli's disease may be treated by resection of the affected part, although the ductal dilatation is usually diffuse. Liver transplantation is a radical but definitive treatment.

Simple cystic disease

Liver cysts are a common coincidental finding in patients undergoing abdominal ultrasound. Radiological findings to

suggest that a cyst is simple are that it is regular, thin walled and unilocular, with no surrounding tissue response and no variation in density within the cyst cavity. If these criteria are confirmed and the cyst is asymptomatic, no further tests or treatment are required. Large cysts may be associated with symptoms of abdominal discomfort possibly related to stretching of the overlying liver capsule, acute pain associated with haemorrhage in the cyst, or may present as right upper quadrant abdominal mass. Aspiration of the cyst contents under radiological guidance provides a sample for culture, microscopy and cytology, and allows the symptomatic response to cyst drainage to be assessed. Aspiration alone is usually associated with cyst and symptom recurrence, in which case more definitive treatment is required. Laparoscopic deroofing is the treatment of choice for large symptomatic cysts and is associated with good long-term symptomatic relief.

Polycystic liver disease

This is a congenital abnormality associated with cyst formation within the liver and often other abdominal organs, principally the pancreas and kidney. Those associated with renal cysts may have autosomal dominant inheritance. The cysts are often asymptomatic and incidental findings on ultrasound. They usually have no effect on organ function and require no specific treatment. Massive polycystic disease of the liver is rare, but can give rise to discomfort or pain. This often responds to treatment with simple analgesics. Severe pain often indicates haemorrhage into a cyst, which may be confirmed by ultrasound or CT scan. Cyst discomfort that is not adequately controlled by oral analgesics may be treated by open or laparoscopic fenestration of the liver cysts, although the results are less favourable than with simple cysts. Ultimately, massive polycystic liver disease may require liver transplantation.

LIVER INFECTIONS

Viral hepatitis

Viral hepatitis is a major world health problem. In addition to the well-recognised acute and chronic liver diseases produced by hepatitis A, B and C, other hepatitis viruses have been isolated, including hepatitis D, which is usually detected only in patients with hepatitis B virus (HBV) infection, and hepatitis E, which produces a self-limiting hepatitis due to faeco-oral spread similar to hepatitis A (Table 65.5).

Hepatitis A presents with anorexia, weakness and general malaise for several weeks prior to the development of clinical jaundice, often accompanied by tenderness on palpation of an enlarged liver. The condition is spread by the faeco-oral route and often spreads rapidly in closed communities. Liver function tests will be compatible with an acute hepatitis, with elevation of bilirubin and transaminases. Diagnosis is confirmed by the antibody titre to hepatitis A. The condition is virtually always self-resolving, although rarely the viral hepatitis can lead to fulminant liver failure. Once the clinical condition resolves, the liver tends to recover fully, with no functional deficit and no long-term sequelae.

Hepatitis B is a more serious condition in most respects than hepatitis A. Although it can also produce an acute self-resolving hepatitis, the virus is often not cleared and produces chronic hepatitis B causing long-term liver damage, with the

Table 65.5 Liver infections and their treatment.

Condition	Causative agent	Treatment
Viral hepatitis	Hepatitis A, B, C	Supportive, anti-viral agents (lamivudine, interferon, ribavirin) Liver transplant for cirrhosis
Ascending cholangitis	Enteric bacteria Relieve obstruction	Antibiotics (cephalosporin)
Pyogenic liver abscess	<i>Streptococcus milleri</i>	Antibiotics
	<i>Escherichia coli</i>	Aspiration
	<i>Streptococcus faecalis</i>	Drainage
Amoebic liver abscess	Entamoeba	Metronidazole
Hydatid liver disease	Echinococcus	Mebendazole
		Resection/omentoplasty

development of liver cirrhosis and hepatocellular carcinoma. Therefore, patients may present acutely with malaise, anorexia, abdominal pain and clinical jaundice due to active hepatitis, or at a late stage owing to the complications of cirrhosis, most commonly ascites or variceal bleeding. Treatment for acute hepatitis is antivirals and supportive. In patients with cirrhosis, treatment is initially dictated by the specific complication at presentation (see above under Treatment of ascites in chronic liver disease). In established cirrhosis, liver transplantation may be considered if viral eradication or suppression can be achieved with anti-viral agents (e.g. lamivudine). Without viral suppression, death from reinfection of the transplanted liver is common. The hepatitis virus greatly increases the risk of primary liver cancer, which usually appears at the stage when the liver parenchyma has become cirrhotic. The assessment and management of HBV cirrhosis with hepatocellular carcinoma (HCC) is discussed below under Liver tumours.

Hepatitis C has become one of the most common causes of chronic liver disease worldwide and, in many countries, a large percentage of the population has been exposed; 1 per cent of potential blood donors worldwide are hepatitis C virus (HCV) positive. Transmission is often related back to blood transfusion, and routine screening of blood for HCV has only recently been introduced in many countries. Chronic HCV infection is an important health problem because currently there is no vaccine available to prevent the disease and current anti-viral treatment has limitations. As with hepatitis B, it may present as an acute hepatitis or progress to chronic hepatitis which may lead to development of liver cirrhosis and hepatocellular carcinoma. Chronic hepatitis C infection can remain hidden until the development of cirrhosis and the complications of portal hypertension or until development of hepatocellular carcinoma. Acute hepatitis C progresses to chronic infection and cirrhosis in about 20 per cent of cases. Decompensation of cirrhosis suggested by deterioration in liver function, encephalopathy, ascites or bleeding in a patient with known HCV cirrhosis necessitates an urgent assessment for liver transplantation, if available. Reinfection of the graft with HCV after liver transplantation occurs in almost all patients.

Ascending cholangitis

Ascending bacterial infection of the biliary tract is usually associated with obstruction and presents with clinical jaundice, rigors and a tender hepatomegaly. The diagnosis is confirmed by the finding of dilated bile ducts on ultrasound, an obstructive picture of liver function tests and the isolation of an organism from the blood on culture. The condition is a medical emergency, and delay in appropriate treatment results in organ failure secondary to septicaemia. Once the diagnosis has been confirmed, the patient should be commenced on a first-line broad-spectrum antibiotic and rehydrated, and arrangements should be made for urgent endoscopic or percutaneous trans-hepatic drainage of the biliary tree. Biliary stone disease is a common predisposing factor, and the causative ductal stones may be removed at the time of endoscopic cholangiography by endoscopic sphincterotomy.

Pyogenic liver abscess

The aetiology of a pyogenic liver abscess is unexplained in the majority of patients. It has an increased incidence in the elderly, diabetics and the immunosuppressed, who usually present with anorexia, fevers and malaise, accompanied by right upper quadrant discomfort. The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasound or CT scan (Figure 65.17) and is confirmed by aspiration for culture and sensitivity. The most common organisms are *Streptococcus milleri* and *Escherichia coli*, but other enteric organisms such as *S. faecalis*, *Klebsiella* and *Proteus vulgaris* also occur, and mixed growths are common. Opportunistic pathogens include staphylococci. Treatment is with antibiotics and ultrasound-guided aspiration. First-line antibiotics to be used are a penicillin, aminoglycoside and metronidazole or a cephalosporin and metronidazole. Often, repeated aspirations may be necessary. Percutaneous drainage without ultrasound guidance should be avoided as an empyema may follow drainage through the pleural space. A source for the liver abscess should be sought, particularly from the colon. Atypical clinical or radiological findings should raise the possibility of a necrotic neoplasm.

Figure 65.17 Liver abscess. Computed tomography scan showing an air-fluid level and rim enhancement with intravenous contrast typical of a liver abscess. In the adjacent liver is a calcified hydatid cyst.

Amoebic liver abscess

Entamoeba histolytica is endemic in many parts of the world. It exists in vegetative form outside the body and is spread by the faeco-oral route. The most common presentation is with dysentery, but it may also present with an amoebic abscess, the common sites being paracaecal and in the liver. The amoebic cyst is ingested and develops into the trophozoite form in the colon, and then passes through the bowel wall and to the liver via the portal blood. Diagnosis is by isolation of the parasite from the liver lesion or the stool and confirming its nature by microscopy. Often patients with clinical signs of an amoebic abscess will be treated empirically with metronidazole (400–800 mg, three times a day, for 7–10 days) and investigated further only if they do not respond. Resolution of the abscess can be monitored using ultrasound.

Hydatid liver disease

This is a very common condition in countries around the Mediterranean. The causative tapeworm, *Echinococcus granulosus*, is present in the dog intestine, and ova are ingested by humans and pass in the portal blood to the liver. Liver abscesses are often large by the time of presentation with upper abdominal discomfort or may present after minor abdominal trauma as an acute abdomen due to rupture of the cyst into the peritoneal cavity. Diagnosis is suggested by the finding of a multiloculated cyst on ultrasound and is further supported by the finding of a floating membrane within the cysts on CT scan (Figure 65.18). Active cysts contain a large number of smaller daughter cysts (Figure 65.19), and rupture can result in these implanting and growing within the peritoneal cavity. Liver cysts can also rupture through the diaphragm producing an empyema, into the biliary tract producing obstructive jaundice, or into the stomach. Clinical and radiological diagnosis can be supported by serology for antibodies to hydatid antigen in the form of an enzyme-linked immunosorbent assay (ELISA). Treatment is indicated to prevent progressive enlargement and rupture of the cysts. In the first instance, a course of albendazole or mebendazole may be tried. There are many reports that percutaneous treatment of hydatid cysts is safe and effective. Percutaneous treatment constitutes an initial course of albendazole followed by puncture of the cyst under image guidance, aspiration of the cysts contents, instillation of hypertonic saline in the cyst cavity and reaspiration (PAIR). PAIR should only be attempted if there is no communication with the biliary tree. Failure to respond to medical treatment or percutaneous treatment usually requires surgical intervention. The surgical options range from liver resection or local excision of the cysts to deroofing with evacuation of the contents. Contamination of the peritoneal cavity at the time of surgery with active hydatid daughters should be avoided by continuing drug therapy with albendazole and adding perioperative praziquantel. This should be combined with packing of the peritoneal cavity with 20 per cent hypertonic saline-soaked packs and instilling 20 per cent hypertonic saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. The residual cavity may become infected, and this may be reduced, as may bile leakage, by packing the space with pedicled greater omentum (an omentoplasty). Calcified cysts may well be dead. If doubt exists as to whether a suspected cyst is active, it can be followed on ultrasound, as active cysts gradually become larger and more superficial in the liver. Rupture of daughter hydatids

Figure 65.18 Hydatid liver cyst. Active hydatid disease usually produces a non-calcified liver cyst and, within the cyst, floating layers of the germinal membrane can be seen.

Figure 65.19 Hydatid 'daughter' cysts. These were removed from the bile duct of a patient presenting with obstructive jaundice due to a hydatid liver cyst communicating with the bile duct. Endoscopic removal should also be considered.

into the biliary tract may result in obstructive jaundice or acute cholangitis. This may be treated by endoscopic clearance of the daughter cysts prior to cyst removal from the liver.

LIVER TUMOURS

Surgical approaches to resection of liver tumours

Adequate exposure of the liver is an absolute prerequisite to safe liver surgery. A transverse abdominal incision in the right upper quadrant with a vertical midline extension to the xiphoid provides excellent access to the liver if adequate retraction of the costal margin is employed using a costal margin retractor. If necessary, the incision can be extended across the midline transversely in the left upper quadrant. Thoracoabdominal incisions are no longer required. The procedure for complete mobilisation of the liver is described, although this will not be necessary in all cases. There are many variations in surgical technique.

Mobilisation of the liver

The falciform ligament is first divided and followed along the anterior surface of the liver towards the suprahepatic IVC. The left triangular ligament is divided, facilitated by placing an abdominal pack in front of the oesophagogastric junction. The right triangular ligament is then divided by retraction of the diaphragm away from the right lobe parenchyma. On exposure of the bare area of the liver, the IVC can be seen as it passes behind the liver, and this can be slung above the renal veins below the liver and at the level of the main hepatic veins. Mobilisation of the liver is completed by division of the lesser omentum. Removing the liver from the IVC is achieved by lifting the liver anteriorly to expose the multiple small veins (inferior hepatic veins) passing between the liver parenchyma and the IVC. These should be suture ligated to ensure haemostasis. This proceeds from above the renal veins until the main hepatic veins are reached below the diaphragm.

Dissection of the hilum

The peritoneum overlying the hilar triad is divided. The CBD is then exposed on the free edge of the lesser omentum, mobilisation being facilitated by ligation and division of the cystic duct and artery followed by removal of the gall bladder. Slinging the CBD with an elastic sling allows exposure of the common hepatic artery and dissection of the main right and left branches. These again may be slung to allow the remaining lymphatic tissue surrounding the portal vein to be ligated and divided. The possibility of an aberrant right hepatic artery lying posterior to the bile duct or an accessory left hepatic artery from the left gastric artery in the lesser omentum should be considered and carefully excluded. Dissection of the hilar bile ducts requires careful retraction on segment IV of the liver, and division of the small vessels and bile duct branches passing between segment IV and the confluence of the right and left hepatic ducts.

Division of the parenchyma

Once the liver has been adequately mobilised and the hilar vessels have been exposed, the main inflow vessels and bile duct to the liver lobe to be resected can be divided. The arterial branch should be transfixed with 4/0 Prolene, the bile duct transfixed with 4/0 PDS and the portal vein branch with a 4/0 Prolene suture. Division of the inflow vessels produces a line of demarcation between the right and left liver, passing to the right of and parallel with the falciform ligament. The parenchyma is divided along this plane of demarcation commencing by diathermy of the liver capsule. The ultrasound dissector (Cavitron ultrasonic surgical aspirator (CUSA)) is the most common method used for division of the parenchyma. This allows the parenchyma to be divided, leaving the vessels and bile duct branches to be diathermied or ligated depending on their size. Dissection continues on an even plane until the hepatic vein branches are approached from within the liver parenchyma, when they are ligated or stapled, and then divided (Figure 65.20).

Segmental and local resections

These are considered in patients whose liver tumours can be excised with an adequate margin (generally considered to be 1 cm) without a formal right or left lobe liver resection. The segments that can be removed individually are those shown in Figure 65.2. Each carries its own blood supply, venous

Figure 65.20 Hepatectomy post-resection. Cut surface of the residual liver following a right hepatectomy in which segments V–VIII have been removed. On the lower edge, the portal vein and bile duct can be visualised.

drainage and bile drainage. The extent of mobilisation of the liver required (described above under Mobilisation of the liver) depends on the segment to be resected. Hilar dissection may not be necessary. Segmental resections are used particularly in patients with HCC and underlying liver disease (e.g. HBV or HCV) to minimise the risk of postoperative liver failure (Figure 65.21). Local resections are principally used for patients with multiple liver metastases when removal of the tumour mass with a minimum margin of 1 cm of normal liver parenchyma is required.

Laparoscopic liver resections

With advances in minimal access surgery, the application of laparoscopic surgery in performing liver resections has evolved considerably. However, success in laparoscopic liver resections requires expertise both in advanced laparoscopic techniques and in liver surgery. Wedge resections of superficial and peripherally located tumours, and left lateral liver resections are commonly performed in most centres. Major right and left hepatectomies are also being performed in selected centres.

Blood loss and transfusion

The reduction of blood loss during liver surgery has been one of the major achievements in the last decade, and resection without blood transfusion is often possible. Better understanding of the segmental anatomy of the liver, better patient selection for surgery, reducing central venous pressure (<10 mmHg) during parenchymal transection have all helped to reduce the need for blood transfusions. Intraoperative cell saver, used in non-cancer cases and during liver transplantation, has reduced the need for autologous blood transfusions. Devices such as the ultrasound dissector have helped, but clamp crushing (Kelly clysis) is equally effective in achieving parenchymal transection with minimal blood loss. Better control of the coagulation cascade has been achieved using TEG (see Figure 65.9), and the anti-fibrinolytic drug aprotinin has significantly reduced bleeding in patients with liver disease and an underlying coagulopathy. Oozing from the resected surface can be reduced by the topical application of fibrin glue or fibrin-impregnated collagen fleece.

Figure 65.21 Segmental resection. Removal of a primary liver tumour by resection of liver segment VI (a and b) in a patient with well-compensated liver cirrhosis.

The main alternative is use of the argon-beam coagulator. Temporary clamping of the portal vein and hepatic artery in the hepatoduodenal ligament (Pringle manoeuvre) can prevent excessive blood loss during parenchymal transection. The optimal duration of the Pringle manoeuvre is unknown, but it can be applied intermittently, e.g. cycles of 15 minutes inflow occlusion followed by 5 minutes of reperfusion, until parenchymal transection is complete.

Benign liver tumours

Haemangiomas

These are the most common liver lesions, and the reported incidence has increased with the widespread availability of diagnostic ultrasound. They consist of an abnormal plexus of vessels, and their nature is usually apparent on ultrasound. If diagnostic uncertainty exists, CT scanning with delayed contrast enhancement shows the characteristic appearance of slow contrast enhancement due to small vessel uptake in the haemangioma. Often, haemangiomas are multiple. Lesions found incidentally require confirmation of their nature and no further treatment. The management of 'giant' haemangiomas is more controversial. Occasional reports of rupture of haemangiomas have led some to consider resection for the large lesions, especially if they appear to be symptomatic. They have little if any malignant

potential, and this is no indication for surgery. Percutaneous biopsy of these lesions should be avoided as they are vascular lesions and may bleed profusely into the peritoneal cavity.

Hepatic adenoma

Hepatic adenomas (Figure 65.22) are rare benign liver tumours. They occur mostly in women of child-bearing age. Imaging by CT or MRI demonstrates a well-circumscribed and vascular solid tumour. They usually develop in an otherwise normal liver. Unfortunately, there are no characteristic radiological features to differentiate these lesions from HCC. Arterial phase CT demonstrates a well-developed peripheral arterialisation of the tumour. Biopsy may be necessary for confirmation and characterisation of the nature of these lesions. These tumours may bleed and are thought to have malignant potential, and resection is therefore the treatment of choice. An association with sex hormones (including the oral contraceptive pill) is well recognised, and regression of symptomatic adenomas on withdrawal of hormone stimulation is well documented.

Focal nodular hyperplasia

This is an unusual benign condition of unknown aetiology in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged

Figure 65.22 Hepatic adenoma. Magnetic resonance imaging scan of a giant hepatic adenoma. These lesions are thought to be premalignant, they may haemorrhage and, in some cases, their growth is sex hormone sensitive. Withdrawal of hormone preparations may allow spontaneous regression.

females, and there is no association with underlying liver disease. Ultrasound shows a solid tumour mass but does not help in discrimination. Contrast CT or/and MRI may show central scarring and evidence of a well-vascularised lesion. Again, these appearances are not specific for focal nodular hyperplasia (FNH). FNH contain both hepatocytes and Kupffer cells. MRI using liver-specific contrast agents, such as gadoxetic acid, which is taken up by hepatocytes and excreted in bile or superparamagnetic iron oxide which is taken up by Kupffer cells, may be useful in determining the hepatocellular origin of FNH and allowing differentiation of FNH from metastatic cancer. Similarly, a sulphur colloid liver scan may be useful, since Kupffer cells take up the colloid. FNH do not have any malignant potential and, once the diagnosis is confirmed, they do not require any treatment.

Surgery for liver metastases

Outcome

The role of surgery in the treatment of colorectal liver metastases is now well established, based on prospective data on resected patients compared with unresected patients with a similar stage of disease. The role of resection of liver metastases from other primary sites has not been well defined. The resectability rate for liver metastases from colorectal cancer is 20–30 per cent. The expected patient survival rate for resection of colorectal metastases is approximately 35 per cent at five years, with few cancer-related deaths beyond this period. Solitary, multiple unilobar and multiple bilobar liver metastases are all considered for resection, although cure rates will vary significantly (Summary box 65.12).

Summary box 65.12

Prognostic factors in patients undergoing resection of colorectal liver metastases

- Stage of primary
- Time from primary resection
- Carcinoembryonic antigen (CEA) level
- Size of largest lesion
- Number of lesions

Staging

This involves defining the extent of the liver involvement with metastases and excluding extrahepatic disease. A standard work up would involve oral and intravenous contrast CT scans of the liver and abdomen, chest CT scan and colonoscopy to look for locally recurrent or synchronous colonic cancers. MRI and PET scanning are useful in the clarification of equivocal lesions. This information should be taken in parallel with a general medical evaluation before deciding on the suitability for surgery of an individual patient. The typical appearance of colorectal liver metastases on contrast CT is shown in Figure 65.23. These patients usually have normal liver parenchyma and therefore tolerate a 60–70 per cent resection of liver parenchyma without risk of postoperative liver failure (Summary box 65.13). Tumour markers are useful but have low specificity. Histological confirmation prior to undertaking surgery is not necessary and percutaneous biopsy of resectable lesions should be avoided as

Figure 65.23 Colorectal liver metastases on computed tomography (CT) scan: (a) after oral contrast CT; (b) after intravenous contrast. The colorectal liver metastasis occupying the entire right lobe of the liver is difficult to visualise on oral contrast CT. The addition of intravenous contrast shows its lack of enhancement and its relationship to the hepatic veins.

there is good evidence that malignant cells can seed along the biopsy track.

Summary box 65.13

Staging and assessment with colorectal liver metastases

- General medical assessment
- CT, PET-CT or MRI of the abdomen/pelvis with contrast (? resectability)
- Chest CT
- Review histology of primary (? risk of local recurrence)
- Colonoscopy
- Liver function tests and tumour markers

Surgical approach

The basic surgical approach to liver resection is outlined above. A search for local recurrent disease, peritoneal deposits and

regional lymph node involvement should be made at the start of the laparotomy. Planar imaging often overlooks peritoneal or superficial liver metastatic deposits. Coeliac node involvement in patients with liver metastases considerably reduces the overall survival whether or not the liver and nodal disease is resected. Intraoperative ultrasound with bimanual palpation of the liver is valuable in assessing the number of lesions and resectability.

Downstaging therapies

There have been major advances in the management of patients with colorectal liver metastases who, until recently, would have been considered 'unresectable' due to the size or distribution of their metastases. Chemotherapy with 5-fluorouracil (5FU) and folinic acid produces a response rate of approximately 30 per cent but, when combined with oxaliplatin, the response rate increases to 50–60 per cent, often with a dramatic size reduction of the lesions. The combination of chemotherapy with monoclonal antibodies (mAbs) that recognise vascular endothelial growth factor (VEGF) receptor or the epidermal growth factor receptor (EGFR) may provide additional benefit. Long-term follow up of patients downstaged with chemotherapy, who have proceeded to resection of their cancers, have shown five-year survival rates of 30–40 per cent.

Patients with bilobar metastases with a lesion centrally within the right lobe and a second lesion peripherally in the left lobe may have resection of their metastases in two stages to allow for regeneration of the liver parenchyma between the procedures. Good long-term survival has been reported for this group of patients.

Portal vein embolisation is a third development to affect patients previously deemed unresectable. Patients who require a right or extended right hepatectomy and in whom the left lobe volumes are congenitally small (<30 per cent of functioning parenchyma) have an increased risk of post-resection liver failure. This can be reduced by preoperative (3–6 weeks) percutaneous embolisation of the right portal vein branch, which produces atrophy of the affected lobe and hypertrophy of the contralateral lobe.

In patients who cannot be rendered resectable, systemic chemotherapy has been shown to produce survival and quality of life benefit. Many techniques are now available that produce local ablation of the tumours, including cryotherapy, interstitial laser hyperthermia, radiofrequency ablation (RFA), microwave therapy, focused ultrasound and electrolytic therapy. These techniques may produce survival benefit along with chemotherapy in the palliative setting, but there is little objective evidence of long-term survival, and they should therefore be restricted to patients who cannot be offered surgical resection (Summary box 65.14).

Summary box 65.14

Strategies for 'unresectable' colorectal liver metastases

- Neoadjuvant chemotherapy
- Anti-VEGF or EGFR monoclonal antibody therapy
- Two-stage liver resection
- Portal vein embolisation
- Ablation techniques

Approximately 15–20 per cent of patients with colorectal cancer present with synchronous liver metastases. However, the timing of resection of the liver metastases in these patients is controversial. For most patients, a staged approach consisting of resection of the colorectal primary first followed by liver resection at a later date is the standard treatment. In selected patients in whom the colorectal primary is small and asymptomatic, the liver resection may be performed first to prevent progression of the liver metastases. In patients requiring minor liver resection for small metastases, simultaneous liver and colorectal resections is safe and effective. Similarly, a right-sided colonic resection which is usually straightforward can be combined with liver resection safely. Combining major liver resection with major colorectal resection is controversial.

Hepatocellular carcinoma

Primary liver cancer (HCC) is one of the world's most common cancers, and its incidence is expected to rise rapidly over the next decade due to the association with chronic liver disease, particularly HBV and HCV. Many patients known to have chronic liver disease are now being screened for the development of HCC by serial ultrasound scans of the liver or serum measurements of alpha-fetoprotein (AFP). Patients often present in middle age, either because of the symptoms of chronic liver disease (malaise, weakness, jaundice, ascites, variceal bleed, encephalopathy) or with the anorexia and weight loss of an advanced cancer. The surgical treatment options include resection of the tumour and liver transplantation. Which option is most appropriate for an individual patient depends on the stage of the underlying liver disease, the size and site of the tumour, the availability of organ transplantation and the management of the immunosuppressed patient.

Staging and clinical assessment of HCC

In addition to a general assessment of the patient's fitness for surgery, crucial information is the severity of the underlying liver disease, based on CTP classification (see Table 65.2) or MELD score, and the size, number and site of the tumour. As chronic liver disease predisposes to these tumours, they are often multifocal by the time of diagnosis. Extensive liver resections in patients with advanced cirrhosis are associated with a high mortality due to liver failure and sepsis. In contrast, extensive resections for HCC in a non-cirrhotic liver are associated with a low risk of liver failure, and resection rather than transplantation would be the treatment option of choice. Tumours often metastasise to the lung and bone and, therefore, a chest CT scan and a bone scan are useful staging investigations. Evidence of intraperitoneal disease is difficult to determine by CT scan, and laparoscopy may be useful for this purpose. The intrahepatic distribution of HCC is equally difficult to determine within the cirrhotic liver. Ultrasound, early arterial phase-enhanced spiral CT scan and contrast MRI are the most useful investigations that are currently available. Wedged hepatic venous pressure (WHVP) measurements are useful in cirrhotic patients. An elevated WHVP suggests portal hypertension and is an independent predictor of poor outcome after liver resection in cirrhotic patients. Indocyanine green (ICG) clearance test is useful to assess liver function preoperatively in cirrhotic patients. Intravenously injected ICG is exclusively eliminated by hepatocytes and excreted into bile and does not enter enterohepatic circulation. The plasma clearance of ICG has been used as an

indicator of hepatic blood flow and hepatic function. Generally, cirrhotic patients who are CTP class A and have a high ICG clearance are suitable for major liver resections.

Surgical approach to HCC

The surgical approach should remove the known cancer with a 1- to 2-cm margin of unaffected liver tissue. In patients with associated chronic liver disease, the volume of liver resected should be minimised to reduce the incidence of postoperative liver failure. Local or segmental resections are preferred to major resections (see Figure 65.21). In carefully selected patients, liver transplantation is an effective treatment. Patients with cirrhosis who have a single HCC less than 5 cm in diameter or multiple HCCs each less than 3 cm, and with no evidence of vascular invasion or extrahepatic spread are ideal candidates for liver transplantation.

Non-surgical therapy for hepatocellular carcinoma

The majority of patients diagnosed with HCC will not be amenable to surgical resection because of the advanced stage of the

cancer or the severity of the underlying liver disease. Those patients awaiting liver transplantation may develop progressive disease before a suitable donor liver is found, because of the long waiting list for transplantation. Patients with unresectable disease can be offered local ablative treatments, such as transarterial embolisation (TAE), transarterial chemoembolisation (TACE), percutaneous ethanol ablation (PEA) or RFA (Figure 65.24). These local ablative treatments may also be used as bridging procedures to liver transplantation.

Follow up and adjuvant treatment

There is little evidence that adjuvant chemotherapy will improve the prognosis of patients following resection of HCC, but trials with the multikinase inhibitor Sorafenib are ongoing. Chemotherapy may damage the function of the liver in those with underlying chronic liver disease. AFP is a clinically useful tumour marker for follow up, although its low sensitivity would suggest that imaging should also be used.

Cholangiocarcinoma

Presentation, pathology and natural history

Bile duct cancers typically present with painless obstructive jaundice. Elderly patients are frequently affected, but patients with PSC may develop these tumours at a much earlier age. These tumours are typically slow growing and often arise at the confluence of the right and left hepatic ducts (Klatskin tumours), eventually invading the liver parenchyma. Cancers at this site are usually fibrous and produce tight duct strictures. Distal bile duct cholangiocarcinomas are more frequently polypoidal and obstruct the lumen of the duct. Investigation, staging and management of bile duct and gall bladder malignancies are discussed in Chapter 67.

LEARNING OBJECTIVES

To understand:

- The function of the spleen
- The common pathologies involving the spleen
- The principles and potential complications of splenectomy
- The potential advantages of laparoscopic splenectomy
- The benefits of splenic conservation
- The importance of prophylaxis against infection following splenectomy

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY**Embryology**

Fetal splenic tissue develops from condensations of mesoderm in the dorsal mesogastrium. This peritoneal fold attaches the dorsal body wall to the fusiform swelling in the foregut that develops into the stomach. This condensation divides the mesogastrium into two parts, one between the fetal splenic tissue and the stomach to form the gastrosplenic ligament and the other between it and the left kidney to form the lienorenal ligament.

Anatomy

The weight of the normal adult spleen is 75–250 g. It lies in the left hypochondrium between the gastric fundus and the left hemidiaphragm, with its long axis lying along the tenth rib. The hilum sits in the angle between the stomach and the kidney and is in contact with the tail of the pancreas. The concave visceral surface lies in contact with these structures, and the lower pole extends no further than the mid-axillary line. There is a notch on the inferolateral border, and this may be palpated when the spleen is enlarged. The tortuous splenic artery arises from the coeliac axis and runs along the upper border of the body and tail of the pancreas, to which it gives small branches. The short gastric and left gastroepiploic branches pass between the layers of the gastrosplenic ligament. The main splenic artery generally divides into superior and inferior branches, which, in turn, subdivide into several segmental branches.

The splenic vein is formed from several tributaries that drain the hilum. The vein runs behind the pancreas, receiving several small tributaries from the pancreas before joining the superior mesenteric vein at the neck of the pancreas to form the portal vein.

The splenic pulp is invested by an external serous and internal fibroelastic coat which is reflected inwards at the hilum onto

the vessels to form vascular sheaths. The lymphatic drainage comprises efferent vessels in the white pulp that run with the arterioles and emerge from nodes at the hilum. These nodes and lymphatics drain via retropancreatic nodes to the coeliac nodes.

Sympathetic nerve fibres run from the coeliac plexus and innervate splenic arterial branches.

Physiology

The splenic parenchyma consists of white and red pulp that is surrounded by serosa and a collagenous capsule with smooth muscle fibres. These penetrate the parenchyma as trabeculae of dense connective tissue fibres rich in collagen and elastic tissue. These, with the reticular framework, support the cells of the spleen and surround the vessels in the splenic pulp. The white pulp comprises a central trabecular artery surrounded by nodules with germinal centres and periarterial lymphatic sheaths that provide a framework filled with lymphocytes and macrophages. Arteries from the central artery and the peripheral 'penicillar' arteries pass into the marginal zone that lies at the edge of the white pulp. Plasma-rich blood that has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed. Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal zone, beyond which lies the red pulp, which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. Red cells must elongate and become thinner to pass from the cords to the sinuses, a process that removes abnormally shaped cells from the circulation (Figure 66.1). As 90 per cent of the blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords, and thence sinuses, splenic pulp pressure reflects the pressure throughout the portal system. The remaining 10 per cent of the blood flow through the spleen bypasses the cords and sinuses by direct arteriovenous communications. The overall flow rate of blood is about 300 mL/min.

Figure 66.1 A central trabecular artery passing through the white pulp into the surrounding red pulp. A blood flow skimming effect results in most of the plasma passing down the branches of the artery while the cells pass in the central trabecular artery directly into the red pulp (courtesy of Professor TG Allen-Mersh, Westminster and Charing Cross Hospitals, London, UK).

FUNCTIONS OF THE SPLEEN

Although the spleen was previously thought to be dispensable, increasing knowledge of its function has led to a conservative approach in the management of conditions involving the spleen. It is now recognised that an incidental splenectomy during the course of another operative procedure increases the risk of complication and death. The surgeon should therefore normally endeavour to preserve the spleen to maintain the following functions:

- **Immune function.** The spleen processes foreign antigens and is the major site of specific immunoglobulin M (IgM) production. The non-specific opsonins, properdin and tuftsin, are synthesised. These antibodies are of B- and T-cell origin and bind to the specific receptors on the surface of macrophages and leukocytes, stimulating their phagocytic, bactericidal and tumoricidal activity.
- **Filter function.** Macrophages in the reticulum capture cellular and non-cellular material from the blood and plasma. This will include the removal of effete platelets and red blood cells. This process takes place in the sinuses and the splenic cords by the action of the endothelial macrophages. Iron is removed from the degraded haemoglobin during red cell breakdown and is returned to the plasma. Removed non-cellular material may include bacteria and, in particular, pneumococci.
- **Pitting.** Particulate inclusions from red cells are removed, and the repaired red cells are returned to the circulation. These include Howell-Jolly and Heinz bodies, which represent nuclear remnants and precipitated haemoglobin or globin subunits, respectively.
- **Reservoir function.** This function in humans is less marked than in other species, but the spleen does contain approximately 8 per cent of the red cell mass. An enlarged spleen may contain a much larger proportion of the blood volume.

- **Cytopenia.** From the fourth month of intrauterine life, some degree of haemopoiesis occurs in the fetal spleen. Stimulation of the white pulp may occur following antigenic challenge, resulting in the proliferation of T and B cells and macrophages. This may also occur in myeloproliferative disorders, thalassaemias and chronic haemolytic anaemias (Summary box 66.1).

Summary box 66.1

Functions of the spleen

- Immune
- Filter function
- Pitting
- Reservoir
- Cytopenia

INVESTIGATION OF THE SPLEEN

Conditions that result in splenomegaly can be diagnosed on the basis of the history and examination findings and from laboratory examination. In haemolytic anaemia, a full blood count, reticulocyte count and tests for haemolysis will determine the cause of the anaemia. Splenomegaly associated with portal hypertension caused by cirrhosis is diagnosed on the history, physical signs of liver dysfunction, abnormal tests of liver function and endoscopic evidence of oesophageal varices. Sinistral or segmental portal hypertension may result from isolated occlusion of the splenic vein by pancreatic inflammation or tumour. As many conditions that cause splenomegaly are associated with lymphadenopathy, investigation should be directed at those disease processes known to be associated with both physical signs. Lymph node biopsy may be required.

Radiological imaging

Plain radiology is rarely used in investigation, but the incidental finding of calcification of the splenic artery or spleen may raise the possible diagnosis of a splenic artery aneurysm, an old infarct, a benign cyst or hydatid disease. Multiple areas of calcification may suggest splenic tuberculosis. Ultrasonography can determine the size and consistency of the spleen, and whether a cyst is present. However, computed tomography (CT) with contrast enhancement is more commonly undertaken to better characterise the nature of the suspected splenic pathology and to exclude other intra-abdominal pathology. Magnetic resonance imaging (MRI) may be similarly useful. Radioisotope scanning is used occasionally to provide information about the spleen. The use of technetium-99m (^{99m}Tc)-labelled colloid is normally restricted to determining whether the spleen is a significant site of destruction of red blood cells.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Splenic agenesis is rare, but is present in 10 per cent of children with congenital heart disease. Polysplenia is a rare condition resulting from failure of splenic fusion.

Splenunculi are single or multiple accessory spleens that are found in approximately 10–30 per cent of the population. They are located near the hilum of the spleen in 50 per cent of cases and are related to the splenic vessels or behind the tail of the pancreas in 30 per cent. The remainder are located in the mesocolon or the splenic ligaments. Their significance lies in the fact that failure to identify and remove these at the time of splenectomy may give rise to persistent disease.

Hamartomas are rarely found in life and vary in size from 1 cm in diameter to masses large enough to produce an abdominal swelling. One form is mainly lymphoid and resembles the white pulp, whereas the other resembles the red pulp.

Non-parasitic **splenic cysts** are rare. Splenic cysts are classified as primary cysts (true) or pseudocysts (secondary) on the basis of the presence or absence of lining epithelium. True cysts form from embryonal rests and include dermoid and mesenchymal

inclusion cysts (Figure 66.2). True cysts of the spleen are very rare and are frequently classified as cystic hemangiomas, cystic lymphangiomas and epidermoid and dermoid cysts. Epidermoid cysts are thought to be of congenital origin and represent 10 per cent of the splenic cysts. They are lined by flattened squamous epithelium and are more frequent in children and young patients. Splenectomy or partial splenectomy is usually considered for cysts larger than 5 cm in diameter. These should be differentiated from false or secondary cysts that may result from trauma and contain serous or haemorrhagic fluid. The walls of such degenerative cysts may be calcified and therefore resemble the radiological appearances of a hydatid cyst. The spleen is also a common site for pseudocyst development following a severe attack of pancreatitis (Figure 66.3). Pseudocysts can easily be diagnosed on scanning, and intervention is normally required for symptomatic lesions that persist following a period of observation.

SPLenic ARTERY ANEURYSM, INFARCT AND RUPTURE

Splenic artery aneurysm

Aneurysms involving the splenic artery are estimated to occur at 0.04–1 per cent of post-mortem examinations. They are twice as common in the female and are usually situated in the main arterial trunk. Although these are generally single, more than one aneurysm is found in a quarter of cases. These may be a consequence of intra-abdominal sepsis and pancreatic necrosis in particular. They are more likely to be associated with arteriosclerosis in elderly patients.

The aneurysm is symptomless unless it ruptures and is more likely to be detected on a plain abdominal x-ray or scan. It is unlikely to be palpable, although a bruit may be present. Rupture is unsuspected in the majority of cases and, as it will generally rupture into the peritoneal cavity, the symptoms mimic those of splenic rupture. Almost half the cases of rupture occur in patients younger than 45 years of age, and a quarter are in pregnant women, usually in the third trimester of pregnancy or at labour. Aneurysmal rupture carries a high mortality rate and

Figure 66.2 Computed tomography scan showing multiple low-density areas in the spleen consistent with multiple benign splenic cysts.

this increases disproportionately in pregnant women with almost inevitable fetal death.

The treatment of choice previously consisted of splenectomy and removal of the diseased artery. Some surgeons advocate ligation of the proximal and distal ends of the sac to allow thrombosis of the aneurysm and partial or complete splenectomy if necessary. The procedure has been performed laparoscopically with success. Embolisation or endovascular stenting following selective splenic artery angiography can be considered. In the younger patient with an asymptomatic splenic artery aneurysm, surgery or interventional radiology is indicated depending on local expertise after CT, MRI or selective coeliac angiography has confirmed the diagnosis (Figure 66.4). In the elderly patient with a calcified aneurysm, there is less risk of rupture, and observation may be preferred. In patients with pancreatic necrosis, the treatment will include drainage of the septic focus.

Splenic infarction

This condition commonly occurs in patients with a massively enlarged spleen from myeloproliferative syndrome, portal hypertension or vascular occlusion produced by pancreatic disease, splenic vein thrombosis or sickle cell disease. The infarct may be asymptomatic or give rise to left upper quadrant and left shoulder tip pain. A contrast-enhanced CT will show the characteristic perfusion defect in the enlarged spleen (Figure 66.5). Treatment is conservative and splenectomy should be considered only when a septic infarct causes an abscess.

Splenic rupture

Splenic rupture (see Chapter 28, Torso trauma) should be considered in any case of blunt abdominal trauma, particularly when the injury occurs to the left upper quadrant of the abdomen. Iatrogenic injury to the spleen remains a frequent complication of any surgical procedure, particularly those in the left upper quadrant when adhesions are present.

Rupture of a malarial spleen

In tropical countries, rupture of a spleen enlarged due to malaria is not uncommon (see below under Tropical splenomegaly). Delayed presentation following a 'trivial' injury is not infrequent. In such patients, splenectomy should be considered

before a perisplenic haematoma ruptures, a complication that is associated with a worse prognosis.

Surgery in such patients is challenging, and early ligation of the splenic vessels along the superior border of the pancreatic body should be considered before disturbing the haematoma.

SPLENOMEGALY AND HYPERSPLENISM

Splenomegaly is a common feature of many disease processes (Table 66.1). It should be borne in mind, however, that many conditions affecting the spleen, such as idiopathic thrombocytopenic purpura, may be associated with enlargement, but the gland is seldom palpable. Few conditions that cause splenomegaly will require splenectomy as part of treatment. **Hypersplenism** is an indefinite clinical syndrome that is characterised by splenic enlargement, any combination of anaemia, leukopenia or thrombocytopenia, compensatory bone marrow hyperplasia and improvement after splenectomy. Careful clinical judgement is required to balance the long- and short-term risks of splenectomy against continued conservative management.

Splenic abscess

Splenic abscess may arise from an infected splenic embolus or in association with typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. In general surgical practice, it may be associated with pancreatic necrosis or other intra-abdominal infection (Figure 66.6). An abscess may rupture and form a left subphrenic abscess or result in diffuse peritonitis. Treatment involves that of the underlying cause and percutaneous drainage of the splenic abscess under radiological guidance is normally required.

Tuberculosis

The diagnosis of tuberculosis should be considered in young adults with splenomegaly presenting with asthenia, loss of weight and fever. Tuberculosis of the spleen may produce portal hypertension or, rarely, cold abscess. Treatment with anti-tuberculous drugs will normally produce improvement. Splenectomy is not normally required and is made difficult by the inflammatory adhesions.

Figure 66.4 Computed tomographic scan showing a pool of contrast in a pseudoaneurysm situated in the tail of the pancreas adjacent to the spleen.

Figure 66.5 Computed tomographic scan showing a splenic infarct (arrows) in a patient with splenomegaly and hypersplenism secondary to portal hypertension and portal vein thrombosis. The varices are evident at the hilus and at the greater curvature of the stomach.

Tropical splenomegaly

Massive splenic enlargement frequently occurs in the tropics from malaria, kala-azar and schistosomiasis. Occasionally, splenomegaly cannot be fully attributed to these diseases. It may result from occult infection or be related to malnutrition. The massive splenomegaly observed in this condition may require removal in those patients disabled by anaemia or local symptoms. Life-long anti-malarial therapy is indicated in malaria-endemic areas.

Schistosomiasis

This condition is prevalent in Africa, Asia and South America. It is caused by infection with *Schistosoma mansoni* in 75 per cent

of cases and by *Schistosoma haematobium* in the remainder. The splenic enlargement may result from portal hypertension associated with hepatic fibrosis, but can also result from hyperplasia induced by the phagocytosis of disintegrated worms, ova and toxin. Splenomegaly can occur at any age. The diagnosis is based on examination of the urine and faeces for ova, abnormal liver function tests and the presence of hypochromic anaemia.

Successful medical treatment of established cases does not result in regression of splenomegaly, and removal of the painful and bulky spleen is indicated where there is no evidence

Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan) and Hong Kong before becoming Physician to the Dreadnought Hospital, Greenwich, London, UK. He is regarded as 'The Father of Tropical Medicine'.

Adolph Weil, 1848–1916, physician, Dorpat (now Tartu), Estonia described leptospirosis icterohaemorrhagica in 1886.

Sir George Frederic Still, 1868–1941, Professor of Diseases of Children, King's College Hospital, London, UK, described chronic articular rheumatism in children in 1896.

Figure 66.6 Computed tomographic scan showing a multiloculated abscess in the enlarged spleen. This was managed successfully by percutaneous drainage under ultrasound guidance.

of hepatic or renal insufficiency. Splenectomy may be required as part of a devascularisation procedure in patients with portal hypertension associated with schistosomiasis.

Leukaemia

Leukaemia should be considered in the differential diagnosis of splenomegaly and the diagnosis is made by examining a blood or marrow film. Splenectomy is reserved for hypersplenism that occurs during the chronic phase of chronic granulocytic leukaemia.

Idiopathic thrombocytopenic purpura

In most cases of idiopathic thrombocytopenic purpura (ITP), the low platelet count results from the development of antibodies to specific platelet membrane glycoproteins that damage the patient's own platelets. It is also known as immune and autoimmune thrombocytopenic purpura. It is defined as isolated thrombocytopenia with normal bone marrow and the absence of other causes of thrombocytopenia. Two distinct clinical types are evident: the acute condition in children and a chronic condition in adults. Acute ITP often follows an acute infection and has a spontaneous resolution within two months. Chronic ITP persists longer than six months without a specific cause being identified. Approximately 50–75 cases per million arise each year in adults compared with 50 cases per million each year in children.

Clinical features

The adult form normally affects females between the ages of 15 and 50 years, although it can be associated with other conditions, including systemic lupus erythematosus, chronic lymphatic leukaemia and Hodgkin's disease. The childhood form is distributed equally between males and females and commonly presents before the age of five years. Purpuric patches (ecchymoses) occur on the skin and mucous membranes. Following trauma or pressure, examination often reveals numbers of petechial haemorrhages in the skin. There is a tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis); in women, menorrhagia and the prolonged bleeding of minor wounds are common. Haemorrhage from the urinary and

gastrointestinal tracts and haemarthrosis are rare. Although intracranial haemorrhage is also uncommon, it is the most frequent cause of death. The diagnosis is made based upon the presence of cutaneous ecchymoses and a positive tourniquet test. The spleen is palpable in fewer than 10 per cent of patients, and the presence of gross splenic enlargement should raise the suspicion of an alternative diagnosis.

Investigations

Coagulation studies are normal, and a bleeding time is not helpful in diagnosis. Platelet count in the peripheral blood film is reduced (usually $<60 \times 10^9/L$). Bone marrow aspiration reveals a plentiful supply of platelet-producing megakaryocytes.

Treatment

The course of the disease differs in children and adults. The disease regresses spontaneously in 75 per cent of paediatric cases following the initial attack. Short courses of corticosteroids in both adult and child are usually followed by recovery. Prolonged steroid therapy should not be continued if this does not produce remission. Splenectomy is usually recommended if a patient has two relapses on steroid therapy or if the platelet count remains low. Generally, this is indicated where the ITP has persisted for more than 6–9 months.

Up to two-thirds of patients will be cured by surgical intervention, and 15 per cent will be improved, but no benefit will be derived in the remainder. The response to steroids predicts a good response to splenectomy. In the acute setting, if severe bleeding has not been controlled by steroid therapy, fresh blood transfusion or transfusion with platelet concentrates before operation is necessary, although these are generally withheld until the splenic vessels have been controlled at operation.

Haemolytic anaemias

There are four causes of haemolytic anaemia that are generally amenable to splenectomy.

Hereditary spherocytosis

Hereditary spherocytosis is an autosomal dominant hereditary disorder characterised by the presence of spherocytic red cells, caused by various molecular defects in the genes that code for alpha- and beta-spectrin, ankyrin, band 3 protein, protein 4.2 and other erythrocyte membrane proteins. These proteins are necessary to maintain the normal biconcave shape of the erythrocyte. Spherocytosis arises essentially from an increase in permeability of the red cell membranes to sodium. As this ion leaks into the cell, the osmotic pressure rises, resulting in swelling and increased fragility of the spherocyte. As the sodium pump has to work harder to rid the cells of sodium, there is greater loss of membrane phospholipid, resulting in an increased fragility of the membrane, and the energy and oxygen requirements increase. A large number of red cells are destroyed in the spleen, where there is a relative deficiency of both glucose and oxygen.

The clinical presentation is generally in childhood, but may be delayed until later life. Mild intermittent jaundice is associated with mild anaemia, splenomegaly and gallstones. Circulating bilirubin is not conjugated with glucuronic acid, and is not therefore excreted in the urine as it is bound to albumin. Excretion of the resulting bilirubin complex by the liver favours the formation of pigment gallstones. Once the disease manifests itself, spontaneous remissions are uncommon; the patient is

often pale and jaundiced at presentation and, in established cases, lassitude and undue fatigue are present.

In some families, the disease is characterised by a severe crisis of red blood cell destruction, during which the erythrocyte count may fall from 4.5×10^6 to $1.5 \times 10^6/\text{mL}$ within a week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor followed by increased jaundice. These episodes may be precipitated by acute infection. Any child with gallstone disease should be investigated for hereditary spherocytosis and a family history sought.

Examination reveals splenomegaly, and the liver may also be palpable. Chronic leg ulcers may arise in adults with the disease.

Haematological investigations include the fragility test. Erythrocytes begin to haemolyse in 0.47 per cent saline solution but, in this condition, haemolysis may occur in 0.6 per cent or even stronger solutions. Immature red blood cells (reticulocytes), which differ from adult cells by possessing a reticulum, are discharged into the circulation by the bone marrow to compensate for the loss of erythrocytes by haemolysis.

Faecal urobilinogen is increased as this route excretes most of the urobilinogen.

Radioactive chromium (^{51}Cr) labelling of the patient's own red cells will demonstrate the severity of red cell destruction. Daily scanning over the spleen will show the degree of red cell sequestration by the spleen. The presence of high levels of splenic radioactivity generally predicts a good response to splenectomy, but this test is used less commonly.

All patients with hereditary spherocytosis should be treated by splenectomy but, in juvenile cases, this is generally delayed until six years of age to minimise the risk of post-splenectomy infection, but before gallstones have had time to form. Ultrasonography should be performed preoperatively to determine the presence or absence of gallstones.

Acquired autoimmune haemolytic anaemia

This condition is divided into immune and non-immune-mediated forms. It may arise following exposure to agents such as chemicals, infection or drugs, e.g. alpha-methyl dopa, or be associated with another disease (e.g. systemic lupus erythematosus). In most instances, the cause is unknown, and red cell survival is reduced because of an immune reaction triggered by immunoglobulin or complement on the red cell surface. This condition is more common in women after the age of 50 years. In half the patients, the spleen is enlarged and, in 20 per cent of cases, pigment gallstones are present.

Anaemia is invariably present and may be associated with spherocytosis because of red cell membrane damage. In the immune type, antibody, which coats the red cells, can be detected by agglutination when anti-human globulin is added to a suspension of the patient's erythrocytes (Coombs' test positive). The disease runs an acute self-limiting course, and no treatment is necessary. Splenectomy should, however, be considered if corticosteroids are ineffective, when the patient is developing complications from long-term steroid treatment or if corticosteroids are contraindicated. Eighty per cent of patients respond to splenectomy.

Thalassaemia (synonyms: Cooley's anaemia, Mediterranean anaemia)

Thalassaemia (Greek, *Thalassa* meaning sea (because the disease occurs in people of Mediterranean origin)) results from a defect

in haemoglobin peptide chain synthesis and is transmitted most commonly as a recessive trait. The disease is really a group of related diseases, alpha, beta and gamma, depending upon which haemoglobin peptide chain's rate of synthesis is reduced. Most patients suffer from betathalassaemia, in which a reduction in the rate of beta-chain synthesis results in a decrease in haemoglobin A. Intracellular precipitates (Heinz bodies) contribute to premature red cell destruction.

Graduations of the disease range from heterozygous thalassaemia minor to homozygous thalassaemia major, which is associated with chronic anaemia, jaundice and splenomegaly. Patients with homozygous thalassaemia major frequently develop clinical signs in the first year of life, and these include retarded growth, enlarged head with slanting eyes and depressed nose, leg ulcers, jaundice and abdominal distension secondary to splenomegaly.

Red cells are small, thin and misshapen and have a characteristic resistance to osmotic lysis. In the more severe forms, nucleated red cells and other immature blood cells are seen. The final diagnosis is by haemoglobin electrophoresis.

Blood transfusion may be required to correct profound anaemia, but the patient may become transfusion dependent because of the development of hypersplenism. Splenectomy is therefore of benefit in patients who require frequent blood transfusion and if haemolytic antibodies have developed as a result.

Sickle cell disease

Sickle cell disease is a hereditary, autosomal recessive haemolytic anaemia occurring mainly among those of African origin in whom the normal haemoglobin A is replaced by haemoglobin S (HbS). The HbS molecule crystallises when the blood oxygen tension is reduced, thus distorting and elongating the red cell. The resulting increased blood viscosity may obstruct the flow of blood in the spleen. Splenic microinfarcts are therefore common.

The sickle cell trait can be detected in 9 per cent of those of African origin, but most are asymptomatic; sickle cell disease occurs in about 1 per cent of Africans. Depending upon the vessels affected by vascular occlusion, patients may complain of bone or joint pain, priapism, neurological abnormalities, skin ulcers or abdominal pain due to visceral blood stasis. The diagnosis is made by the finding of characteristic sickle-shaped cells on blood film, although this investigation has largely been replaced by haemoglobin electrophoresis.

Hypoxia that provokes a sickling crisis should be avoided and is particularly relevant in patients undergoing general anaesthesia. Adequate hydration and partial exchange transfusion may help in a crisis. Splenectomy is of benefit in a few patients in whom excessive splenic sequestration of red cells aggravates the anaemia. Chronic hypersplenism usually occurs in late childhood or adolescence, although *Streptococcus pneumoniae* infection may precipitate an acute form in the first five years of life.

Porphyria

Porphyria is a hereditary error of haemoglobin catabolism in which porphyrinuria occurs. Abdominal crises, characterised by severe intestinal colic and constipation, can be precipitated by the administration of barbiturates. The patient is anaemic and may suffer from photosensitivity; in advanced forms of the disease, neurological and mental symptoms are present. The splenomegaly associated with this condition may be overlooked. The urine may be orange and develops a port-wine colour after

a few hours of exposure to the air. Splenectomy has little role to play in the management of this condition.

Gaucher's disease

This lipid storage disease is characterised by storage of glucocerebroside in the reticuloendothelial system and in the spleen. Enormous splenic enlargement may be associated with yellowish-brown discolouration of the skin on the hands and face, anaemia and conjunctival thickening (pinguecula). Slavonic and Jewish races are more prone to the disease, and the detection of Gaucher cells in the bone marrow confirms the diagnosis. Splenectomy is indicated only for severe symptoms related to the splenomegaly.

Hypersplenism due to portal hypertension

Splenomegaly is an invariable feature of portal hypertension (Figure 66.7) and results in the thrombocytopenia and granulocytopenia observed in these patients. These may be improved if the portal hypertension is relieved by shunt surgery or liver transplantation. Splenectomy would normally be required only in those patients whose segmental portal hypertension has resulted in symptomatic oesophagogastric varices.

Felty's syndrome

Patients with rheumatoid arthritis may develop leukopenia. This is referred to as Felty syndrome if it is extreme and associated with splenomegaly. There is no definite relationship between the severity of the arthritic changes and the leukopenia and splenomegaly. Splenectomy produces only a transient improvement in the blood picture, but rheumatoid arthritis may respond to steroid therapy to which it had previously become resistant.

NEOPLASMS

Haemangioma is the most common benign tumour of the spleen and may rarely develop into a haemangiosarcoma that is managed by splenectomy. The spleen is rarely the site of metastatic disease. Lymphoma is the most common cause of neoplastic enlargement, and splenectomy may play a part in

Figure 66.7 Computed tomographic scan showing an enlarged spleen in a patient with portal hypertension secondary to portal vein thrombosis. Clot is evident within the lumen of the portal vein (black arrow), and large varices (white arrows) are present at the splenic hilum.

Figure 66.8 Magnetic resonance imaging (MRI) scan showing massive hepatosplenomegaly secondary to myelofibrosis. Note the prominent portal system and the left kidney, which is superimposed over the grossly enlarged spleen.

its management. Splenectomy may be required to achieve a diagnosis in the absence of palpable lymph nodes or to relieve the symptoms of gross splenomegaly. However, the need for staging laparoscopy has largely receded with the advent of CT scanning. Its use has been restricted to those patients in whom a definite histological diagnosis of intra-abdominal disease will affect management. Thus, selected patients with stage IA or IIA Hodgkin's disease may be candidates for staging laparotomy or laparoscopy. In the absence of obvious liver or intra-abdominal nodal disease, splenectomy is an integral part of the staging procedure to exclude splenic involvement, which would alter the method of treatment.

Myelofibrosis results from an abnormal proliferation of mesenchymal elements in the bone marrow, spleen, liver and lymph nodes. Most patients present over the age of 50 years, and the spleen may produce pain owing to its gross enlargement (Figure 66.8) or from splenic infarcts. Splenectomy reduces the need for transfusion and may relieve the discomfort resulting from the splenomegaly.

SPLENECTOMY

The common indications for splenectomy are:

- trauma resulting from an accident or during a surgical procedure, as for example during mobilisation of the oesophagus, stomach, distal pancreas or splenic flexure of the colon;
- removal en bloc with the stomach as part of a radical gastrectomy or with the pancreas as part of a distal or total pancreatectomy;
- to reduce anaemia or thrombocytopenia in spherocytosis, idiopathic thrombocytopenic purpura or hypersplenism;
- in association with shunt or variceal surgery for portal hypertension (Summary box 66.2).

Summary box 66.2**Indications for splenectomy**

- Trauma
 - Accidental
 - Operative
- Oncological
 - Part of en bloc resection
 - Diagnostic
 - Therapeutic
- Haematological
 - Spherocytosis
 - Purpura (ITP)
 - Hypersplenism
- Portal hypertension
 - Variceal surgery

Preoperative preparation

In the presence of a bleeding tendency, transfusion of blood, fresh-frozen plasma, cryoprecipitate or platelets may be required. Coagulation profiles should be as near normal as possible at operation, and platelets should be available for patients with thrombocytopenia at operation and in the early postoperative period.

Antibiotic prophylaxis appropriate to the operative procedure should be given and consideration should be given to the risk of post-splenectomy sepsis (see below under Postoperative complications).

Technique of open splenectomy

Most surgeons use a midline or transverse left subcostal incision for open splenectomy. Rarely, a thoracoabdominal incision may be necessary for a massive spleen that is adherent to the diaphragm. Passage of a nasogastric tube following induction of the anaesthetic enables the stomach to be emptied.

In elective splenectomy, the gastrosplenic ligament is opened up, and the short gastric vessels are divided. The splenic vessels at the superior border of the pancreas are suture-ligated. The

posterior surface of the spleen is exposed, the posterior leaf of the lienorenal ligament divided with long curved scissors, and the spleen rotated medially along with the tail and body of the pancreas (Figure 66.9). The pancreas is separated from the hilar vessels, which are ligated and divided. Accessory splenic tissue in the splenic hilum or omentum should be excluded by a careful search at operation. There is no need to drain the wound if haemostasis is secured adequately.

The segmental vasculature of the spleen does make it possible to undertake limited resection of the parenchyma. Haemostasis can be achieved by ligation of, or application of, metal clips to intrasplenic vessels, and by careful application of topical haemostatic agents or mesh. Conservative splenic surgery is therefore possible in some cases of splenic trauma and other pathology, such as splenic cysts.

Technique of laparoscopic splenectomy

The patient is placed on the right side with the space between the left ilium and costal margin exposed. Placement of access ports is often determined by the size of the patient and the spleen. Insufflation of the abdomen can be performed once access is obtained through an incision 1 cm from the costal margin at the left mid-clavicular line. A further trocar is inserted close to the costal margin below the xiphoid. A 12-mm trocar is inserted at a similar distance from the costal margin at the posterior axillary line. The splenocolic ligament is divided to give access to the lower splenic pole. The spleen is separated from the kidney and diaphragm before the gap between the splenic hilum and the tail of the pancreas is enlarged. The spleen is elevated to expose the splenic hilum, which is secured and divided with an endoscopic vascular stapler (Figure 66.10). Two or three applications of the instrument may be required to secure the hilum and the short gastric vessels. Any remaining attachments to the diaphragm are divided before a self-retaining opening bag is introduced through the incision of the open laparoscopy after removal of the 12-mm port. The spleen is placed in the bag, the mouth of which is pulled out of the abdominal opening before the spleen is crushed and retrieved with an instrument. The operation may be undertaken as a hand-assisted procedure particularly when the spleen is grossly enlarged.

Figure 66.9 Diagrammatic view of the approach required to divide the short gastric vessels anteriorly and the lienorenal ligament posteriorly.

Figure 66.10 Photograph showing a stapling gun across the hilum of spleen for division of the splenic vessels during laparoscopic splenectomy.

Postoperative complications

Immediate complications specific to splenectomy include haemorrhage resulting from a slipped ligature. Haematemesis from gastric mucosal damage and gastric dilatation is uncommon. Left basal atelectasis is common, and a pleural effusion may be present. Adjacent structures at risk during the procedure include the stomach and pancreas. A fistula may result from damage to the greater curvature of the stomach during ligation of the short gastric vessels. Damage to the tail of the pancreas may result in pancreatitis, a localised abscess or a pancreatic fistula. Postoperative thrombocytosis may arise and, if the blood platelet count exceeds $1 \times 10^6/\text{mL}$, prophylactic aspirin is recommended to prevent axillary or other venous thrombosis.

Post-splenectomy septicæmia may result from *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* and *Escherichia coli*. The risk is greater in the young patient, in splenectomised patients treated with chemoradiotherapy and in patients who have undergone splenectomy for thalassaemia, sickle cell disease and autoimmune anaemia or thrombocytopenia.

Opportunist post-splenectomy infection (OPSI) is a major concern. Published guidelines emphasise that most infections after splenectomy could be avoided through measures that include offering patients appropriate and timely immunisation, antibiotic prophylaxis, education and prompt treatment of infection. The benefit of prophylactic antibiotics in this setting remains controversial. It is thought that children who have undergone splenectomy before the age of five years should be treated with a daily dose of penicillin until the age of ten years. Prophylaxis in older children should be continued at least until the age of 16 years, but its use is less well defined in adults. Furthermore, compliance is problematic in the long term but, as the risk of overwhelming sepsis is greatest within the first 2–3 years after splenectomy, it seems reasonable to give prophylaxis during this time. However, all patients with compromised immune function should receive prophylaxis. Satisfactory oral prophylaxis can be obtained with penicillin, erythromycin or amoxicillin, or co-amoxiclav. Suspected infection can be treated intravenously with these same antibiotics and cefotaxime, ceftriaxone or chloramphenicol in patients allergic to penicillin and cephalosporins. If elective splenectomy is planned, consideration should be given to vaccinating against pneumococcus, meningococcus C (both repeated every five years) and *H. influenzae* type B (Hib) (repeated every ten years). The latter two vaccines are commonly delivered as a combined preparation. Yearly influenza vaccination has been recommended as there is some evidence that it may reduce the risk of secondary bacterial infection. Such vaccinations should be administered at least 2 weeks before elective surgery or as soon as possible after recovery from surgery but before discharge from hospital. Pneumococcal vaccination is recommended in those patients aged over two years. *Haemophilus influenzae* type b vaccination is recommended

irrespective of age. Asplenic patients should carry a medical alert and an up-to-date vaccination card. They require specific advice regarding travel and animal handling. Patients who have undergone splenectomy and are travelling to countries where malaria is present are strongly advised to use all physical anti-mosquito barriers, as well as anti-malarial therapy, since they are at increased risk of severe malaria. Overwhelming post-splenectomy sepsis due to *Capnocytophaga canimorsus* may result from dog, cat or other animal bites.

In the trauma victim, vaccination can be given in the postoperative period, and the resulting antibody levels will be protective in the majority of cases. Antibody levels are, however, less than 50 per cent of those achieved if vaccination is given in the presence of an intact spleen. Protection following vaccination is not always guaranteed (Summary box 66.3).

Summary box 66.3

Splenectomy

- Remember preoperative immunisation
- Prophylactic antibiotics in the long term
- OPSI is a real clinical danger
- Splenic conservation should be considered

The spleen dislikes, distrusts and devours spheroidal red cells.

Arthur Rendle Short 1880–1953

Professor of Surgery, University of Bristol, UK

CHAPTER 67

The gall bladder and bile ducts

LEARNING OBJECTIVES

- To understand the anatomy and physiology of the gall bladder and bile ducts
- To be familiar with the pathophysiology and management of gallstones
- To be aware of unusual disorders of the biliary tree
- To be aware of malignant disease of the gall bladder and bile ducts

SURGICAL ANATOMY AND PHYSIOLOGY

The gall bladder lies on the underside of the liver in the main liver scissura at the junction of the right and left lobes of the liver. The relationship of the gall bladder to the liver varies between being embedded within the liver substance to being suspended by a mesentry. It is a pear-shaped structure, 7.5–12 cm long, with a normal capacity of about 25–30 mL. The anatomical divisions are a fundus, a body and a neck that terminates in a narrow infundibulum. The muscle fibres in the wall of the gall bladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

The cystic duct is about 3 cm in length, but the length is variable. The lumen is usually 1–3 mm in diameter. The mucosa of the cystic duct is arranged in spiral folds known as the 'valves of Heister' and the wall is surrounded by a sphincteric structure called the 'sphincter of Lütken'. The cystic duct joins the supraduodenal segment of the common hepatic duct in 80 per cent of cases; however, the anatomy may vary and the junction may be much lower in the retroduodenal or even retropancreatic part of the bile duct. Occasionally, the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct (see below).

The common hepatic duct is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The common bile duct is about 7.5 cm long and formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

- **Supraduodenal portion.** About 2.5 cm long, running in the free edge of the lesser omentum.
- **Retroduodenal portion.**
- **Intraduodenal portion** lies in a groove, but at times in a tunnel, on the posterior surface of the pancreas.

- **Intraduodenal portion** passes obliquely through the wall of the second part of the duodenum, where it is surrounded by the sphincter of Oddi, and terminates by opening on the summit of the ampulla of Vater.

The cystic artery, a branch of the right hepatic artery, usually arises behind the common hepatic duct (Figure 67.1).

Figure 67.1 The anatomy of the gall bladder and bile ducts. Note the arrangement of the arterial tree.

Abraham Vater, 1684–1751, Professor of Anatomy and Botany, Wittenberg, Germany.

Figure 67.2 (a) Usual anatomy of Calot's triangle; (b) tortuous common hepatic artery; (c) tortuous right hepatic artery with short cystic artery; (b) and (c) are examples of so-called 'caterpillar turn' or 'Moynihan's hump' which if not recognised can lead to inadvertent arterial injury or bleeding during cholecystectomy.

The most dangerous anomalies are where the hepatic artery takes a tortuous course on the front of the origin of the cystic duct (Figure 67.2b), or the right hepatic artery is tortuous and the cystic artery short (Figure 67.2c). The tortuosity is known as the 'caterpillar turn' or 'Moynihan's hump'. This variation is the cause of many problems during a difficult cholecystectomy with inflammation in the region of the cystic duct.

Lymphatics

The lymphatic vessels of the gall bladder (subserosal and submucosal) drain into the cystic lymph node of Lund (the sentinel lymph node), which lies in the fork created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver, and to the coeliac lymph nodes. The subserosal lymphatic vessels of the gall bladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gall bladder to the liver.

Surgical physiology

Bile is produced by the liver and stored in the gall bladder from which it is released into the duodenum. As it leaves the liver, it is composed of 97 per cent water, bile salts (cholic and cheno-

Occasionally, an accessory cystic artery arises from the gastroduodenal artery. In 15 per cent of cases, the right hepatic artery and/or the cystic artery cross in front of the common hepatic duct and the cystic duct.

Calot's triangle or the hepatobiliary triangle is the space bordered by the cystic duct inferiorly, the common hepatic artery medially and the superior border of the cystic artery. This was described in 1891 by Jean-François Calot. It is an important surgical landmark and should be identified by surgeons performing a cholecystectomy to avoid damage to the extrahepatic biliary system (Figure 67.2a).

Jean-François Calot, 1861–1944, surgeon, Paris, France.

Fred Bates Lund, 1865–1950, surgeon, Boston City Hospital, Boston, MA, USA.

Berkeley George Andre Moynihan, (Lord Moynihan of Leeds), 1865–1936, Professor of Clinical Surgery, University of Leeds, UK. Moynihan felt that English surgeons knew little about the work of their colleagues both at home and abroad. Therefore, in 1909, he established a small travelling club which, in 1929, became the Moynihan Chirurgical Club. It still exists. He took a leading part in founding the British Journal of Surgery in 1913 and became the first chairman of the editorial committee until his death.

deoxycholic acids, deoxycholic and lithocholic acids), phospholipids, cholesterol and bilirubin. The liver excretes bile at a rate estimated to be approximately 40 mL/hour. About 95 per cent of bile salts are reabsorbed in the terminal ileum (enterohepatic circulation).

FUNCTIONS OF THE GALL BLADDER

The gall bladder is a reservoir for bile. During fasting, resistance to flow through the sphincter of Oddi is high, and bile excreted by the liver is diverted to the gall bladder. After feeding, the resistance to flow through the sphincter is reduced, the gall bladder contracts and the bile enters the duodenum. These motor responses of the biliary tract are in part effected by the hormone cholecystokinin.

The second function of the gall bladder is concentration of bile by active absorption of water, sodium chloride and bicarbonate by the mucous membrane of the gall bladder. The hepatic bile which enters the gall bladder becomes concentrated 5–10 times, with a corresponding increase in the proportion of bile salts, bile pigments, cholesterol and calcium.

The third function of the gall bladder is the secretion of mucus – approximately 20 mL is produced per day. With complete obstruction of the cystic duct in an otherwise healthy gall bladder, a mucocoele may develop as a result of ongoing mucus secretion by the gall bladder mucosa.

RADIOLOGICAL INVESTIGATION OF THE BILIARY TRACT

Plain x-rays

The skillfully taken plain x-ray of the gall bladder will show radiopaque gallstones in 10 per cent of patients (Figure 67.3). Rarely, the centre of a stone may contain radiolucent gas in a

Figure 67.3 Plain radiograph showing radiopaque stones in the gall bladder. Radiopaque stones are rare (10 per cent).

Figure 67.4 Porcelain gall bladder.

triradiate or biradiate fissure and this gives rise to characteristic dark shapes on a radiograph – the ‘Mercedes-Benz’ or ‘seagull’ sign.

A plain x-ray may also show the rare cases of calcification of the gall bladder, a so-called ‘porcelain’ gall bladder (Figure 67.4). Today, this is more commonly seen on computed tomography (CT) scan (Figure 67.5). The importance of this appearance is that it is associated with carcinoma in up to 25 per cent of cases and is an indication for cholecystectomy. Gas may be seen in the wall of the gall bladder (emphysematous cholecystitis) (Figure 67.6). Gas in the biliary tree may be seen after endoscopic sphincterotomy or surgical anastomosis.

Figure 67.5 Computed tomography scan demonstrating calcification in the gall bladder wall (‘porcelain gall bladder’).

Figure 67.6 Gas in the gall bladder and gall bladder wall (*Clostridium perfringens*). Emergency surgery is indicated.

Figure 67.7 Ultrasound examination. Multiple gallstones noted within the gall bladder.

Oral cholecystography and intravenous cholangiography

Oral and intravenous cholecystography are of interest for historical purposes only, as they were relatively inaccurate and have been replaced by more accurate imaging modalities.

Ultrasonography

Transabdominal ultrasonography (Figures 67.7 and 67.8) is the initial imaging modality of choice as it is accurate, readily available, inexpensive and quick to perform. However, it is operator dependent and may be suboptimal due to excessive body fat and intraluminal bowel gas. It can demonstrate biliary calculi, the size of the gall bladder, the thickness of the gall bladder wall, the presence of inflammation around the gall bladder, the size of the common bile duct and, occasionally, the presence of stones within the biliary tree.

Figure 67.8 Ultrasound examination. Gallstones noted at the neck of the gall bladder with associated acoustic shadowing.

Figure 67.9 Endoscopic ultrasonography. CBD, common bile duct; PD, pancreatic duct.

In the patient who presents with obstructive jaundice, ultrasonography is particularly helpful as it can identify intra- and extrahepatic biliary dilation and often the level of obstruction. In addition, the cause of the obstruction may also be identified, such as gallstones in the gall bladder, common hepatic or common bile duct stones or lesions in the wall of the common bile duct suggestive of a cholangiocarcinoma or enlargement of the pancreatic head indicative of a pancreatic carcinoma.

Endoscopic ultrasonography utilises a specially designed endoscope with an ultrasound transducer at its tip which allows the gastroenterologist to visualise the liver and biliary tree from within the stomach and duodenum (Figure 67.9). It is an accurate technique to determine the presence of stones in the common bile duct. In addition, it has been shown to be highly accurate in diagnosing and staging both pancreatic and periampullary cancers.

Radioisotope scanning

Technetium-99m (^{99m}Tc)-labelled derivatives of iminodiacetic acid (HIDA, IODIDA) when injected intravenously are selectively taken up by the retroendothelial cells of the liver and excreted into the bile. This allows for visualisation of the biliary tree and gall bladder. In 90 per cent of normal individuals the gall bladder is visualised within 30 minutes following injection with 100 per cent being seen within 1 hour (Figure 67.10). The bowel is seen usually within 1 hour in the majority of patients. Non-visualisation of the gall bladder is suggestive of acute cholecystitis. If the patient has a contracted gall bladder as often seen in chronic cholecystitis, the gall bladder visualisation may be reduced or delayed.

Biliary scintigraphy may also be helpful in diagnosing bile leaks and iatrogenic biliary obstruction. When there is a suspicion of a bile leak following a cholecystectomy, radioisotope imaging should be one of the initial investigations performed. It can identify and quantitate the leak thus helping the surgeon determine whether or not an operative or conservative approach is warranted. If available, endoscopic retrograde cholangiopancreatography (ERCP) should be considered as this is both diagnostic and potentially therapeutic. The most common bile leak following cholecystectomy is from the cystic duct. This can be treated by the gastroenterologist placing a biliary endoprosthesis (stent) in the common bile duct across the origin of the cystic duct.

Computed tomography

Unlike ultrasonography, CT is less affected by body habitus and is not operator dependent. It allows visualisation of the liver, bile ducts, gall bladder and pancreas (Figure 67.11) and is particularly useful in detecting hepatic and pancreatic lesions and is the modality of choice in the staging of cancers of the liver, gall bladder, bile ducts and pancreas. It can identify the extent of the primary tumour and defines its relationship to other organs and blood vessels (Figure 67.12). In addition, the presence of enlarged lymph nodes or metastatic disease can be seen.

Improvements in CT technology, such as multidetector scanners, which allow for three-dimensional reconstruction of the biliary tree have led to greater diagnostic accuracy and have increased the accuracy of CT in assessing benign disease.

Figure 67.10 Dimethyl iminodiacetic acid (HIDA) scan.

Figure 67.11 Computed tomography scan demonstrating a gallstone within the gall bladder (arrowed).

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is an imaging technique based on the principles of nuclear magnetic resonance used to image the gall bladder and biliary system. It is non-invasive and can provide either cross-sectional or projection images (Figures 67.13 and 67.14). Excellent images can be obtained of the biliary tree demonstrating ductal obstruction, strictures or other intraductal abnormalities. Images comparable to those obtained at ERCP or percutaneous transhepatic cholangiography (PTC) can be achieved non-invasively without the potential complications of either technique.

Endoscopic retrograde cholangiopancreatography

This technique remains widely used as both a diagnostic and therapeutic modality. Using a side-viewing endoscope the ampulla of Vater can be identified and cannulated. Injection

of water-soluble contrast directly into the bile duct provides excellent images of the ductal anatomy (Figure 67.15) and can identify causes of obstruction, such as calculi (Figure 67.16) or malignant strictures (Figure 67.17). While the widespread availability of ultrasound and MRCP has reduced its diagnostic use, ERCP still has a real role in the assessment of the patient with obstructive jaundice. In this group of patients, it is especially useful in determining the cause and level of obstruction.

During ERCP, bile aspirates can be sent for cytological and microbiological examination, and endoluminal brushings can be taken from strictures for cytological studies. Therapeutic interventions, such as stone removal or stent placement to relieve the obstruction, can be performed. Thus, ERCP has evolved into a mainly therapeutic rather than a diagnostic technique.

Percutaneous transhepatic cholangiography

This is an invasive technique in which the bile ducts are cannulated directly. It is only undertaken once a bleeding tendency has been excluded and the patient's prothrombin time is normal. Antibiotics should be given prior to the procedure. Usually, under fluoroscopic control, a needle (the Chiba or Okuda needle) is introduced percutaneously into the liver substance. Under radiological control (either ultrasound or CT), a bile duct is cannulated. Successful entry is confirmed by contrast injection or aspiration of bile. Water-soluble contrast medium is injected to demonstrate the biliary system. Multiple images can

Figure 67.17 Endoscopic retrograde cholangiopancreatography: partial occlusion of the bile duct by a malignant stricture (arrow).

be taken demonstrating areas of strictures or obstruction (Figure 67.18). Bile can be sent for cytology. In addition, this technique enables placement of a catheter into the bile ducts to provide external biliary drainage or the insertion of indwelling stents. The scope of this procedure can be further extended by leaving

Figure 67.18 Transhepatic cholangiogram showing a stricture of the common hepatic duct (courtesy of Miss Phyllis George, FRCS, London, UK).

the drainage catheter *in situ* for a number of days and then dilating the track sufficiently for a fine flexible choledochoscope to be passed into the intrahepatic biliary tree in order to diagnose strictures, take biopsies and remove stones.

In general, if a malignant stricture at the level of the confluence of the right and left hepatic ducts or higher is suspected in a jaundiced patient, a PTC is preferred to ERCP as successful drainage is more likely (Summary box 67.1).

Summary box 67.1

Investigation of the biliary tree

- Ultrasound: stones and biliary dilation
- Plain radiograph: calcification
- MRCP: anatomy and stones
- MDR-CT scan: anatomy liver, gall bladder and pancreas cancer

Figure 67.20 Peroperative cholangiography. Technique of introducing contrast.

Intraoperative imaging techniques

Peroperative cholangiography

During open or laparoscopic cholecystectomy, a catheter can be placed in the cystic duct and contrast injected directly into the biliary tree. The technique defines the anatomy and in the main is used to exclude the presence of stones within the bile ducts (Figures 67.19, 67.20 and 67.21). A single x-ray plate or image intensifier can be used to obtain and review the images intraoperatively. Irrespective of the technique used, the operating table should be tilted head down approximately 20° to facilitate

Figure 67.21 Peroperative cholangiography. (a) Normal common bile duct: gentle infusion of contrast which passes without hindrance into the duodenum. (b) The common bile duct is dilated with multiple stones. Contrast is seen to reflux into the pancreatic duct. A sphincterotomy was performed.

filling of the intrahepatic ducts. In addition, care should be taken when injecting contrast not to introduce air bubbles into the system as these may give the appearance of stones and lead to a false-positive result.

Operative biliary endoscopy (choledochoscopy)

At operation, a flexible fiberoptic endoscope can be passed via the cystic duct into the common bile duct enabling stone identification and removal under direct vision. The technique can be combined with an x-ray image intensifier to ensure complete clearance of the biliary tree. After exploration of the bile duct, a tube can be left in the cystic duct remnant or in the common bile duct (a T-tube) and drainage of the biliary tree established. After 7–10 days, a track will be established. This track can be used for the passage of a choledochoscope to remove residual stones in the awake patient in an endoscopy suite. This technique is invaluable in the management of difficult stone disease and prevents the excessive prolongation of an operative exploration of the common bile duct.

Laparoscopic ultrasonography

At laparoscopy, the use of a laparoscopic ultrasound probe can be used to image the extrahepatic biliary system. It is a useful technique in biliary and pancreatic tumour staging as it can identify the primary tumour and determine its relationship to major vessels, such as the hepatic artery, superior mesenteric artery, portal vein and superior mesenteric vein.

CONGENITAL ABNORMALITIES OF THE GALL BLADDER AND BILE DUCTS

Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, which is destined to become the gall bladder and cystic duct. The embryonic hepatic duct sends out many branches which join up the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally, recanalisation subsequently occurs and bile begins to flow. During early fetal life, the gall bladder is entirely intrahepatic.

Absence of the gall bladder

Occasionally, the gall bladder is absent. Failure to visualise the gall bladder is not necessarily a pathological problem.

The Phrygian cap

The Phrygian cap (Figure 67.22) is present in 2–6 per cent of cholecystograms and may be mistaken for a pathological deformity of the organ. 'Phrygian cap' refers to hats worn by the people of Phrygia, an ancient country of Asia Minor; it was rather like a *liberté* cap of the French Revolution.

Floating gall bladder

The gall bladder may hang on a mesentery, which makes it liable to undergo torsion.

Absence of the cystic duct

This is usually a pathological, as opposed to an anatomical, anomaly and indicates the recent passage of a stone or the

presence of a stone at the lower end of the cystic duct, which is ulcerating into the common bile duct. The main danger at surgery is damage to the bile duct, and particular care to identify the correct anatomy is essential before division of any duct.

Low insertion of the cystic duct

The cystic duct opens into the common bile duct near the ampulla. All variations of this anomaly can occur (Figure 67.23). At operation, they are not important. Dissection of a cystic duct which is inserted low in the bile duct should be avoided, as removal will damage the blood supply to the common bile duct and can lead to stricture formation.

An accessory cholecystohepatic duct

Ducts passing directly into the gall bladder from the liver are not uncommon. Larger ducts should be closed, but before doing so the precise anatomy should be carefully ascertained to ensure a right hepatic duct is not being ligated (Figure 67.23).

EXTRAHEPATIC BILIARY ATRESIA

Aetiology and physiology

Atresia is present in approximately 1 per 12 000 live births, and affects males and females equally. The extrahepatic bile

Figure 67.22 The main variations in gall bladder and cystic duct anatomy. (a) Double gall bladder; (b) septum of the gall bladder; 1 is the most common, the so-called 'Phrygian cap'; (c) diverticulum of the gall bladder; (d) variations in cystic duct insertion.

Figure 67.23 Patterns of cystic duct anatomy – note segment VI drainage into the cystic duct and the drainage of the right posterior (RP) sectorial duct into the neck of the gall bladder, or an accessory duct, the so-called duct of Luschka.

ducts are progressively destroyed by an inflammatory process which starts around the time of birth. The aetiology is unclear. Intrahepatic changes also occur and eventually result in biliary cirrhosis and portal hypertension. Untreated, death from the consequences of liver failure occurs before the age of three years.

The inflammatory destruction of the bile ducts has been classified into three main types (Figure 67.24):

- type I: atresia restricted to the common bile duct;
- type II: atresia of the common hepatic duct;
- type III: atresia of the right and left hepatic ducts.

In about 20 per cent of cases, associated anomalies include cardiac lesions, polysplenia, situs inversus, absent vena cava and a preduodenal portal vein.

Figure 67.24 Classification of biliary atresia. Gall bladder filling provides a clue to the type of atresia.

Clinical features

About one-third of patients are jaundiced at birth. In all, however, jaundice is present by the end of the first week and deepens progressively. Liver function tests show an obstructive pattern with elevated bilirubin and alkaline phosphatase. The meconium may be a little bile stained, but later the stools are pale and the urine is dark. Prolonged steatorrhoea gives rise to osteomalacia (biliary rickets). Pruritus is severe. Clubbing and skin xanthomas, probably related to a raised serum cholesterol, may be present.

Differential diagnosis

This includes any form of jaundice in a neonate giving a cholestatic picture. Examples are α_1 -antitrypsin deficiency, cholestasis associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. Neonatal hepatitis is the most difficult to differentiate. Both extrahepatic biliary atresia and neonatal hepatitis are associated with giant cell transformation of the hepatocytes. Liver biopsy and radionuclide excretion scans are essential.

Treatment

Patent segments of proximal bile duct are found in 10 per cent of type I lesions. A direct Roux-en-Y hepaticojejunostomy will achieve bile flow in 75 per cent, but progressive fibrosis results in disappointing long-term results. A simple biliary-enteric anastomosis is not possible in the majority of cases in which the proximal hepatic ducts are either very small (type II) or atretic (type III). These are treated by the Kasai procedure, in which radical excision of all bile duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein creating a portoenterostomy. The chances of achieving effective bile drainage after portoenterostomy are maximal when the operation is performed before the age of 8 weeks, and approximately 90 per cent of children whose bilirubin falls to within the normal range can be expected to survive for ten years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40 per cent of patients. Repeated attacks lead to hepatic fibrosis and 50 per cent of long-term survivors develop portal hypertension, with one-third having variceal bleeding.

Liver transplantation should be considered in children in whom a portoenterostomy is unsuccessful. Results are improving with 70–80 per cent alive two to five years following transplant.

CONGENITAL DILATATION OF THE INTRAHEPATIC DUCTS (CAROLI'S DISEASE)

This rare condition is characterised by multiple irregular sacular dilations of the intrahepatic ducts separated by segments of normal or stenotic ducts with a normal extrahepatic biliary system. The aetiology is unknown, but it is considered to be hereditary. It can be divided into a simple and periportal fibrotic type. The periportal fibrotic type presents in childhood and is associated with biliary stasis, stone formation and cholangitis, whereas the simple type presents later with episodes of

abdominal pain and biliary sepsis. Associated conditions include congenital hepatic fibrosis, polycystic liver and, rarely, cholangiocarcinoma. The mainstays of treatment are antibiotics for the cholangitis and the removal of calculi. As the condition can be limited to one lobe of the liver, lobectomy may be indicated.

Choledochal cyst

Cystic disease of the biliary system is rare. Choledochal cysts are congenital dilations of the intra- and/or extrahepatic biliary system. The pathogenesis is unclear. Anomalous junctions of the biliary pancreatic junction are frequently observed, but whether or not these play a role in the pathogenesis of the condition is unclear. Todani and colleagues proposed a classification of cystic disease of the biliary tract (Figure 67.25). Type I cysts are the most common and account for approximately 75 per cent of patients.

Patients may present at any age with jaundice, fever, abdominal pain and a right upper quadrant mass on examination, however, 60 per cent of cases are diagnosed before the age of ten years. Pancreatitis is not an infrequent presentation in adults. Patients with choledochal cysts have an increased risk of developing cholangiocarcinoma with the risk varying directly with the age at diagnosis.

Ultrasonography will confirm the presence of an abnormal cyst and magnetic resonance imaging (MRI/MRCP) will reveal the anatomy, in particular the relationship between the lower end of the bile duct and the pancreatic duct. CT is also useful for delineating the extent of the intra- or extrahepatic dilation.

Radical excision of the cyst is the treatment of choice with reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Complete resection of the cyst is important because of the association with the development of cholangiocarcinoma. Resection and Roux-en-Y reconstruction is also associated with a reduced incidence of stricture formation and recurrent cholangitis.

TRAUMA

Injuries to the gall bladder and extrahepatic biliary tree are rare. They occur as a result of blunt or penetrating abdominal trauma. Operative trauma is perhaps more frequent than external trauma. The physical signs are those of an acute abdomen. Management depends on the location and extent of the biliary and associated injury. In the stable patient, a transected bile duct is best repaired by a Roux-en-Y choledochojejunostomy. Injuries to the gall bladder can be dealt with by cholecystectomy.

TORSION OF THE GALL BLADDER

This is very rare and requires a long mesentery, which often occurs in an older patient with a large mucocoele of the gall bladder. The patient presents with extreme pain and an acute abdomen. Immediate exploration is indicated, with cholecystectomy as the only treatment.

GALLSTONES (CHOLELITHIASIS)

Gallstones are the most common biliary pathology. It is estimated that gallstones affect 10–15 per cent of the population in western societies. They are asymptomatic in the majority of

Figure 67.25 Classification of types of choledochal cyst. Type Ia and b: diffuse cystic. Note extension into pancreas of type Ib. Type II: diverticulum of common bile duct. Type III: diverticulum within pancreas. Type IV: extension into the liver. Type V: cystic dilatation only of the intrahepatic ducts.

cases (>80 per cent). In the UK, the prevalence of gallstones at the time of death is estimated to be 17 per cent and may be increasing. Approximately, 1–2 per cent of asymptomatic patients will develop symptoms requiring surgery per year, making cholecystectomy one of the most common operations performed by general surgeons.

Causal factors in gallstone formation

Gallstones can be divided into three main types: cholesterol, pigment (brown/black) or mixed stones. In the United States and Europe, 80 per cent are cholesterol or mixed stones, whereas in Asia, 80 per cent are pigment stones. Cholesterol or mixed stones contain 51–99 per cent pure cholesterol plus an admixture of calcium salts, bile acids, bile pigments and phospholipids.

Cholesterol, which is insoluble in water, is secreted from the canalicular membrane in phospholipid vesicles. Whether cholesterol remains in solution depends on the concentration of phospholipids and bile acids in bile, and the type of phospholipid and bile acid. Micelles formed by the phospholipid hold cholesterol in a stable thermodynamic state. When bile is supersaturated with cholesterol or bile acid concentrations are low, unstable unilamellar phospholipid vesicles form, from which cholesterol crystals may nucleate, and stones may form. The process of gallstone formation is complex (Figure 67.26), and many areas remain unclear. Obesity, high-caloric diets and certain medications (e.g. oral contraceptives) can increase secretion of cholesterol and supersaturate the bile increasing the lithogenicity of bile. Resection of the terminal ileum, which diminishes the enterohepatic circulation, will deplete the bile acid pool and result in cholesterol supersaturation. Nucleation of cholesterol monohydrate crystals from multilamellar vesicles is a crucial step in gallstone formation. Abnormal emptying of the gall bladder function may aid the aggregation of nucleated cholesterol crystals; hence, removing gallstones without removing the gall bladder inevitably leads to gallstone recurrence.

Pigment stone is the name used for stones containing less

than 30 per cent cholesterol. There are two types – black and brown. Black stones are largely composed of an insoluble bilirubin pigment polymer mixed with calcium phosphate and calcium bicarbonate. Overall, 20–30 per cent of stones are black. The incidence rises with age. Black stones are associated with haemolysis, usually hereditary, spherocytosis or sickle cell disease. For reasons that are unclear, patients with cirrhosis have a higher instance of pigmented stones.

Brown pigment stones contain calcium bilirubinate, calcium palmitate and calcium stearate, as well as cholesterol. Brown stones are rare in the gall bladder. They form in the bile duct and are related to bile stasis and infected bile. Stone formation is related to the deconjugation of bilirubin deglucuronide by bacterial β -glucuronidase. Insoluble unconjugated bilirubinate precipitates. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts, such as endoprosthesis (stents), or parasites, such as *Clonorchis sinensis* and *Ascaris lumbricoides*.

Clinical presentation

Gallstones may remain symptomatic, being detected incidentally as imaging is performed for other symptoms. If symptoms occur, patients typically complain of right upper quadrant or epigastric pain, which may radiate to the back. This may be described as colicky, but more often is dull and constant. Other symptoms include dyspepsia, flatulence, food intolerance, particularly to fats, and some alteration in bowel frequency. Biliary colic is typically present in 10–25 per cent of patients. This is described as a severe right upper quadrant pain which ebbs and flows associated with nausea and vomiting. Pain may radiate to the chest. The pain is usually severe and may last for minutes or even several hours. Frequently, the pain starts during the night and wakes the patient. Minor episodes of the same discomfort may occur intermittently during the day. Dyspeptic symptoms may coexist and be worse after such an attack. As the pain resolves, the patient improves and is able to eat and drink

again, often only to suffer further episodes. It is of interest that a patient may have several episodes of this nature over a period of a few weeks and then no more trouble for some months. Jaundice may result if the stone migrates from the gall bladder and obstructs the common bile duct. Rarely, a gallstone can lead to bowel obstruction (gallstone ileus) (Summary box 67.2).

Summary box 67.2

Effects and complications of gallstones

- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis
- Empyema of the gall bladder
- Mucocoele
- Perforation
- Biliary obstruction
- Acute cholangitis
- Acute pancreatitis
- Intestinal obstruction (gallstone ileus)

When the symptoms do not resolve, but progress to continued pain with fever and leukocytosis, the diagnosis of acute cholecystitis should be considered. The differential diagnosis is given in Summary box 67.3.

Summary box 67.3

- Common
 - Appendicitis
 - Perforated peptic ulcer
 - Acute pancreatitis
- Rare
 - Acute pyelonephritis
 - Myocardial infarction
 - Pneumonia – right lower lobe

Figure 67.26 Factors associated with gallstone formation.

Diagnosis

A diagnosis of gallstone disease is based on the history and physical examination with confirmatory radiological studies, such as transabdominal ultrasonography and radionuclide scans (see above under Radiological investigation of the biliary tract). In the acute phase, the patient may have right upper quadrant tenderness that is exacerbated during inspiration by the examiner's right subcostal palpation (Murphy's sign). A positive Murphy's sign suggests acute inflammation and may be associated with a leukocytosis and moderately elevated liver function tests. A mass may be palpable as the omentum walls off an inflamed gall bladder. Fortunately in the majority of cases, the process is limited by the stone slipping back into the body of the gall bladder and the contents of the gall bladder escaping by way of the cystic duct. This achieves adequate drainage of the gall bladder and enables the inflammation to resolve.

If resolution does not occur, an empyema of the gall bladder may result. The wall may become necrotic and perforate, with development of localised peritonitis. The abscess may then perforate into the peritoneal cavity with a septic peritonitis –

however, this is uncommon, because the inflamed gall bladder is usually localised by omentum which contains the perforation.

A palpable, non-tender gall bladder (Courvoisier's sign) portends a more sinister diagnosis. This usually results from a distal common duct obstruction secondary to a peripancreatic malignancy. Rarely, a non-tender, palpable gall bladder results from complete obstruction of the cystic duct with reabsorption of the intraluminal bile salts and secretion of uninfected mucus secreted by the gall bladder epithelium leading to a mucocoele of the gall bladder.

Treatment

Most consider that it is safe to observe patients with asymptomatic gallstones, with cholecystectomy reserved for patients who develop symptoms or complications. However, prophylactic cholecystectomy may be considered for diabetic patients, those with congenital haemolytic anaemia and those patients who are undergoing bariatric surgery for morbid obesity as it has been found in these groups that the risk of developing symptoms is increased. For patients with biliary colic or cholecystitis, cholecystectomy is the treatment of choice if there are no medical contraindications.

Experience shows that in more than 90 per cent of cases, the symptoms of acute cholecystitis subside with conservative measures. Non-operative treatment is based on four principles:

- Nil per mouth (NPO) and intravenous fluid administration until the pain resolves.
- Administration of analgesics.
- Administration of antibiotics. As the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than its concentration in bile. A broad-spectrum antibiotic effective against Gram-negative aerobes is most appropriate (e.g. cefazolin, cefuroxime or gentamicin).
- Subsequent management. When the temperature, pulse and other physical signs show that the inflammation is subsiding, oral fluids are reinstated followed by regular diet. Ultrasonography is performed to confirm the diagnosis. If jaundice is present, an MRCP is performed to exclude choledocholithiasis. If there is any concern regarding the diagnosis or presence of complications, such as perforation, a CT should be performed. Cholecystectomy may be performed on the next available list, or the patient may be allowed home to return later when the inflammation has completely resolved.

Conservative treatment must be abandoned if the pain and tenderness increase; depending on the status of the patient, either operative intervention and cholecystectomy should be performed or if the patient has comorbid conditions, a percutaneous cholecystostomy can be performed by a radiologist under ultrasound control. This will usually rapidly relieve symptoms, however an interval cholecystectomy will be required once the patient's condition has stabilised.

The timing of surgery in acute cholecystitis remains controversial with many units favouring an early intervention within the first week, whereas others suggest that a delayed approach is preferable. Early cholecystectomy during acute cholecystitis appears to be safe and shortens the total hospital stay.

Provided that the operation is undertaken within 5–7 days of

the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are achieved. Nevertheless, the conversion rate in laparoscopic cholecystectomy is higher in acute than in elective surgery. If an early operation is not indicated, one should wait approximately 6 weeks for the inflammation to subside before operating.

EMPHYEMA OF THE GALL BLADDER

Empyema may be a sequel of acute cholecystitis or the result of a mucocoele becoming infected. The gall bladder is distended with pus. The optimal treatment is drainage (cholecystostomy, see above under Gallstones (cholelithiasis)) and, later, cholecystectomy.

Acalculous cholecystitis

Acute and chronic inflammation of the gall bladder can occur in the absence of stones and give rise to a clinical picture similar to calculous cholecystitis. Some patients have non-specific inflammation of the gall bladder, whereas others have one of the cholecystoses (see below). Acute acalculous cholecystitis is particularly seen in critically ill patients and those recovering from major surgery, trauma and burns. The diagnosis is often missed and the mortality rate is high.

THE CHOLECYSTOSES (CHOLESTEROSIS, POLYPOSIS, ADENOMYOMATOSIS AND CHOLECYSTITIS GLANDULARIS PROLIFERANS)

This is a relatively uncommon group of conditions affecting the gall bladder, in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

Cholesterosis ('strawberry gall bladder')

In the fresh state, the interior of the gall bladder looks something like a strawberry; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (Figure 67.27). It may be associated with cholesterol stones.

Figure 67.27 The interior of a strawberry gall bladder (cholesterosis) (courtesy of Dr Sanjay P Thakur, Patna, India).

Cholesterol polyposis of the gall bladder

Cholecystography shows negative shadows in a functioning gall bladder, or on ultrasound there is a well-defined polyp present. These are due either to cholesterol polyposis or adenomatous change. With high resolution ultrasonography, they are seen more frequently, and surgery is advised only if there is a change in size over time or are larger than 1 cm.

Cholecystitis glandularis proliferans (polyp, adenomyomatosis and intramural diverticulosis)

Figure 67.28 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous. All layers of the gall bladder wall may be thickened, but sometimes an incomplete septum forms that separates the hyperplastic from the normal. Intraparietal 'mixed' calculi may be present. These can be complicated by an intramural, and later extramural, abscess and potentially fistula formation. If symptomatic, the patient is treated by cholecystectomy.

Diverticulosis of the gall bladder

Diverticulosis of the gall bladder is usually manifest as black pigment stones impacted in the outpouchings of the lacunae of Luschka. Diverticulosis of the gall bladder may be demonstrated by cholecystography, especially when the gall bladder contracts after a fatty meal. There are small dots of contrast medium just within and outside the gall bladder (Figure 67.29). A septum may also be present to be distinguished from the Phrygian cap. The treatment is cholecystectomy.

Typhoid infection of the gall bladder

Salmonella typhi or *S. typhimurium* can infect the gall bladder. Acute cholecystitis can occur. More frequently, chronic cholecystitis occurs, the patient being a typhoid carrier excreting the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid!). It is debatable whether the stones are secondary to the *Salmonella* cholecystitis or whether pre-existing stones predispose the gall bladder to chronic infection. *Salmonellae* can, however, frequently be cultured from these stones. Treatment with ampicillin and cholecystectomy are indicated. In cases of penicillin allergy, a quinolone antibiotic can be used.

Figure 67.28 Types of cholecystitis glandularis proliferans (polypus, intramural or diverticular stones and fistula).

Figure 67.29 Cholecystogram showing diverticulosis with dots of contrast medium in the gall bladder wall.

CHOLECYSTECTOMY

Preparation for operation

After appropriate history taking and assessment of the patient's fitness for the procedure, a full blood count and biochemical profile should be performed to exclude anaemia and to identify abnormal liver function. A blood coagulation screen should be checked if there is a history of jaundice or liver function is abnormal. Prophylactic antibiotics should be administered either with the premedication or at the time of induction of anaesthesia. A second-generation cephalosporin is appropriate. Subcutaneous heparin or anti-embolic stockings should be prescribed. The patient must sign a consent form to indicate that he or she is fully aware of the procedure being undertaken, alternative options and the risks involved and complications that may occur (Summary box 67.4).

Summary box 67.4

Preparation for operation

- Full blood count
- Renal profile and liver function tests
- Prothrombin time
- Chest x-ray and electrocardiogram (if over 45 years or medically indicated)
- Antibiotic prophylaxis
- Deep vein thrombosis prophylaxis
- Informed consent

Laparoscopic cholecystectomy

The preparation and indications for cholecystectomy are the same whether it is performed by laparoscopy or by open techniques. Laparoscopic cholecystectomy is the procedure of choice for the majority of patients with gall bladder disease. The key, as in open surgery, is the identification and safe dissection of Calot's triangle (Figure 67.30).

Figure 67.30 Operative image of a laparoscopic cholecystectomy. Laparoscopic forceps (arrow) are used to dissect Calot's triangle.

The patient is placed supine on the operating table. Following induction and maintenance of general anaesthetic, the abdomen is prepared in a standard fashion. Pneumoperitoneum is established. A number of techniques are described. The author's preference is to use an open subumbilical cutdown with direct visualisation of the peritoneum to place the initial port. This port will function as the camera port. An angled telescope (30°) is preferred. Many surgeons use a 'closed' technique using a Verres needle to establish pneumoperitoneum prior to placing the initial trocar.

Additional operating ports are inserted in the subxiphoid area and in the right subcostal area. The patient is placed in a reverse Trendelburg position slightly rotated to the left. This exposes the fundus of the gall bladder which is retracted towards the diaphragm. The neck of the gall bladder is then retracted towards the right iliac fossa exposing Calot's triangle. This area is laid widely open by dividing the peritoneum on the posterior and on the anterior aspect. The cystic duct is carefully defined, as is the cystic artery. The gall bladder is separated from the liver bed for about 2 cm to allow for confirmation of the anatomy. Unless there are specific indications (see below), a routine cholangiogram is not performed. However, if doubt exists regarding the anatomy, a cholangiogram is warranted. Once the anatomy is clearly defined and the triangle of Calot has been laid widely open, the cystic duct and artery are clipped and divided. The gall bladder is then removed from the gall bladder bed by sharp or cautery dissection and once free removed via the umbilicus.

Open cholecystectomy

For patients in whom a laparoscopic approach is not indicated or in whom conversion from a laparoscopic approach is required an open cholecystectomy is performed.

Either an upper midline or a short right upper transverse incision is made centred over the lateral border of the rectus muscle. The gall bladder is appropriately exposed and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatis. These packs may be retracted using the hand of the assistant ('It is the left hand of the assistant that does all the work' – Moynihan), or, alternatively, a stabilised ring retractor can be used to keep the packs in position.

An artery or Duval forceps is placed on the infundibulum of

the gall bladder and the peritoneum overlying Calot's triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gall bladder and the fat in the triangle of Calot carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is cleaned down to the common bile duct, whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear and the cystic duct is then divided between ligatures (Figure 67.31). The gall bladder is then dissected away from the gall bladder bed.

Some golden rules to observe in case of difficulty:

- When the anatomy of the triangle of Calot is unclear, blind dissection should stop.
- Bleeding adjacent to the triangle of Calot should be controlled by pressure and not by blind clipping or clamping.
- When there is doubt about the anatomy, a retrograde or 'fundus-first' cholecystectomy dissecting on the gall bladder wall down from the fundus to the cystic duct can be helpful.
- If the cystic duct is densely adherent to the common bile duct and there is the possibility of a Mirizzi syndrome (a stone ulcerating through the neck of the gall bladder into the common hepatic duct), the infundibulum of the gall bladder should be opened, the stone removed and the infundibulum oversewn. Attempts to completely dissect out the cystic duct will only lead to common hepatic or common bile duct injury.
- A cholecystostomy is rarely indicated, but, if it has to be done, as many stones as possible should be extracted and a large Foley catheter (14 F) placed in the fundus of the gall bladder with a direct track externally. By so doing, should stones be left behind in the gall bladder, these can be subsequently extracted with a choledochoscope.

Indications for choledochotomy

In an environment in which neither the modern diagnostic armamentarium described at the beginning of this chapter nor peroperative cholangiography is available, it is well to remember the traditional indications for choledochotomy, which are:

- palpable duct stones;
- jaundice or a history of jaundice or cholangitis;
- a dilated common bile duct;
- abnormal liver function tests, in particular a raised alkaline phosphatase.

Figure 67.31 Ligatures are passed and tied around the cystic artery and cystic duct. The grey shaded area represents Calot's triangle.

Unless the expertise is available, it is probably inadvisable to perform a choledochotomy laparoscopically; rather one should rely on endoscopic techniques or convert to an open operation. The incidence of symptomatic stones in the bile duct varies from 5 to 8 per cent. These can, in the main, be dealt with endoscopically without resort to opening the duct. However, current trials suggest that in experienced hands the morbidity of the two techniques is identical.

Complications of cholecystectomy

Recovery after laparoscopic cholecystectomy is associated with less pain, enhanced recovery and faster return to normal activity. The majority of patients undergoing an elective procedure can have this procedure performed as a day case, avoiding hospital admission. Any untoward symptoms in the postoperative period, such as fevers, chills or abdominal pain require immediate investigation.

The operative mortality for cholecystectomy is less than 1 per cent. Factors increasing the risk for postoperative mortality include advanced age, comorbid conditions and acute presentation. Complications can occur in 10–15 per cent of cases. Serious complications of laparoscopic cholecystectomy fall into two major areas: access complications or bile duct injuries. The latter are rare occurring in approximately 0.5 per cent of cases. In the main, biliary injury results from poor dissection and failure to adequately define the surgical anatomy. Controversy exists as to whether or not the use of operative cholangiography reduces the incidence of bile duct injury. The majority of surgeons use cholangiography only in selected cases.

Patients who develop jaundice in the postoperative period require urgent investigation. This is especially true if the jaundice is associated with infection, a condition called cholangitis.

The first step in management is to undertake an immediate ultrasound scan. This will demonstrate whether there is intra- or extrahepatic ductal dilation. The anatomy needs to be defined by either an ERCP or a MRCP. The former will also allow therapeutic manoeuvres such as removal of an obstructing stone or insertion of a stent across a biliary leak. If a fluid collection is present in the subhepatic space drainage catheters may be required. These can be inserted under radiological control or if this expertise is not available at open operation. Small biliary leaks will usually resolve spontaneously, especially if there is no distal obstruction. Should the common bile duct be damaged, the patient should be referred to an appropriate expert for reconstruction of the duct.

About 15 per cent of injuries to the bile ducts are recognised at the time of operation, in the remaining 85 per cent of cases, the injury declares itself postoperatively by: (1) a profuse and persistent leakage of bile if drainage has been provided, or bile peritonitis if such drainage has not been provided; and (2) deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Any postoperative elevation in serum bilirubin or suggestion of duct damage requires investigation and the nature of the bile duct injury clarified. The surgical repair and subsequent outcome is related to the level of injury, which is determined using the Bismuth classification.

In a debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an

intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient has improved, definitive surgery can be undertaken. The principles of surgical repair are maintenance of duct length and restoration of biliary drainage. For benign stricture or duct transection, the preferred treatment is immediate Roux-en-Y choledochojejunostomy performed by an experienced surgeon. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable alternative provided that the services of an experienced endoscopist are available. The outcome of such surgery is good, with 90 per cent patients having no further cholangitis or stricture formation.

Late symptoms after cholecystectomy

In up to 15 per cent of patients, cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a 'post-cholecystectomy' syndrome. However, such problems are usually related to the preoperative symptoms and are merely a continuation of those symptoms. Full investigation should be undertaken to confirm the diagnosis and exclude the presence of a stone in the bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by MRCP or ERCP, the latter which has the added advantage that if a stone is in the common bile duct it can be removed.

Post-cholecystectomy choledocholithiasis

Duct stones may occur many years after a cholecystectomy or be related to the development of new pathology, such as infection of the biliary tree or infestation by *Ascaris lumbricoides* or *Clinorchis sinensis*. Any obstruction to the flow of bile can give rise to stasis with the formation of stones within the duct. The consequences of duct stones are either obstruction to bile flow or infection. Stones in the bile ducts are more often associated with infected bile (80 per cent) than are stones in the gall bladder.

Symptoms

The patient may be asymptomatic but usually has bouts of pain, jaundice and fever. The patient is often ill and feels unwell. The term 'cholangitis' is given to the triad of pain, jaundice and fevers sometimes known as 'Charcot's triad'.

Signs

Tenderness may be elicited in the epigastrium and the right hypochondrium. In the jaundiced patient, it is useful to remember Courvoisier's law – 'in obstruction of the common bile duct due to a stone, distension of the gall bladder seldom occurs; the organ usually is already shrivelled'. In obstruction from other causes, distension is common by comparison. However, if there is no disease in the gall bladder and the obstruction is due to a cancer of the ampulla, pancreas or bile duct, then the gall bladder may well be distended.

Management

It is essential to determine whether the jaundice is due to liver disease, disease within the duct, such as sclerosing cholangitis, or obstruction. Ultrasound scanning, liver function tests, liver biopsy if the ducts are not dilated, and MRI or ERCP will identify the nature of the obstruction.

The patient may be ill. Pus may be present within the biliary tree and liver abscesses may be developing. Full supportive measures are required with rehydration, attention to clotting, exclusion of diabetes and starting the appropriate broad-spectrum antibiotics. As soon as resuscitation has taken place, relief of the obstruction is essential. Endoscopic papillotomy is the preferred first technique with a sphincterotomy, removal of the stones using a Dormia basket or the placement of a stent if stone removal is not possible (Figure 67.32 and 67.33). If this technique fails, percutaneous transhepatic cholangiography can be performed to provide drainage and subsequent percutaneous choledochoscopy. Surgery, in the form of choledochotomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques (Figure 67.34).

Choledochotomy

When faced with a sick patient whose investigations show that the cause of the cholangitis is stones in the common bile duct and minimally invasive techniques for stone extraction are not available, the surgeon has no alternative but to undertake a laparotomy. The aim of this surgery is to drain the common bile duct and remove the stones through a longitudinal incision in the duct. When the duct is clear of stones, a T-tube is inserted and the duct closed around it; the long limb is brought out on the right side and the bile allowed to drain externally. When the bile has become clear and the patient recovered, a cholangiogram is performed by the radiologist. If residual stones are found, the tube is left in place for 6 weeks so that the track is 'mature'. The radiologist can then use the track for percutaneous removal of the stones (Figure 67.34). Once the radiologist has removed the tube, the track will close and the patient make a rapid recovery.

Stricture of the bile duct

The causes of benign biliary stricture are given in Summary box 67.5. Bile duct strictures may be investigated radiologically (Summary box 67.6).

Summary box 67.5

Causes of benign biliary stricture

- Congenital
 - Biliary atresia
- Bile duct injury at surgery
 - Cholecystectomy
 - Choledochotomy
 - Gastrectomy
 - Hepatic resection
 - Transplantation
- Inflammatory
 - Stones
 - Cholangitis
 - Parasitic
 - Pancreatitis
 - Sclerosing cholangitis
 - Radiotherapy
- Trauma
- Idiopathic

Figure 67.32 Endoscopic retrograde cholangiopancreatography showing multiple stones in the common bile duct in a patient who presented with jaundice 4 days following laparoscopic cholecystectomy.

Summary box 67.6

Radiological investigation of biliary strictures

- Ultrasonography
- Cholangiography via T-tube, if present
- ERCP
- MRCP
- Percutaneous transhepatic cholangiography (Figure 67.18)
- CT scan

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is an idiopathic fibrosing inflammatory condition of the biliary tree which affects both

Figure 67.33 (a) Endoscopic sphincterotomy; (b) extraction of a stone from the bile duct through the ampulla.

intrahepatic and extrahepatic ducts. It is of unknown origin, but the association of hypergammaglobulinaemia and elevated markers such as smooth muscle antibodies and antinuclear factor suggest an immunological basis. The majority of patients are between 30 and 60 years. There appears to be a male predominance and a strong association with inflammatory bowel disease especially ulcerative colitis.

Common symptoms include right upper quadrant discomfort, jaundice, pruritus, fever, fatigue and weight loss. Investigation reveals a cholestatic pattern to the liver function tests with elevation of the serum alkaline phosphatase and gamma glutamyl transferase and smaller rises in the aminotransferases. Bilirubin values can be variable and may fluctuate. Imaging studies such as MRCP or ERCP may demonstrate stricturing and beading of the bile ducts (Figure 67.35). A liver biopsy is helpful in confirming the diagnosis and may help guide therapy by excluding cirrhosis. The important differential diagnoses are secondary sclerosing cholangitis and cholangiocarcinoma. The latter condition may be very difficult to diagnose and a high index of suspicion is required especially in the setting of an unexplained deterioration.

Medical management with antibiotics, vitamin K, cholestyramine, steroids and immunosuppressant drugs, such as azathioprine, is generally unsuccessful. Endoscopic stenting of dominant strictures and, in selected patients with predominantly extrahepatic disease, operative resection may be worthwhile. For patients with cirrhosis, liver transplantation is the best option. Five-year survival following transplantation in high-volume centres is in excess of 80 per cent.

PARASITIC INFESTATION OF THE BILIARY TRACT

Biliary ascariasis

The round worm, *Ascaris lumbricoides*, commonly infests the intestine of inhabitants of Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include strictures, suppurative cholangitis, liver abscesses and empyema of the gall bladder. In the uncomplicated case, antispasmodics can be given to relax the sphincter of Oddi and the worm will return to the small intestine to be dealt with by antihelminthic drugs. Operation may be necessary to remove the worm or deal with complications. Worms can be extracted via the ampulla of Vater by ERCP.

Figure 67.34 Extraction of a stone from the common bile duct by the Burhenne technique. (a) A T-tube *in situ* with a stone in the duct. (b) A steerable catheter has been manipulated into the duct and a basket placed around the stone. (c) The stone being extracted from the bile duct along the T-tube track.

Clonorchiasis (Asiatic cholangiohepatitis)

The disease is endemic in the Far East. The fluke, up to 25 mm long and 5 mm wide, inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occur. Many cases are asymptomatic. Complications include biliary

Figure 67.35 Sclerosing cholangitis in a patient with ulcerative colitis visualised by endoscopic retrograde cholangiopancreatography.

pain, stones, cholangitis, cirrhosis and bile duct carcinoma. Choledochotomy and T-tube drainage and, in some cases, choledochoduodenostomy are required. Because a process of recurrent stone formation is set up, a choledochojejunostomy with a Roux loop fixed to the adjacent abdominal wall is performed in some centres to allow easy subsequent access to the duct system.

Hydatid disease

A large hydatid cyst may obstruct the hepatic ducts. Sometimes, a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see Chapters 6 and 65).

TUMOURS OF THE BILE DUCT

Benign tumours of the bile duct

These are uncommon and need to be distinguished from other benign conditions.

They may be an incidental finding on imaging. For symptomatic patients, the duration of symptoms may vary from a few days to months and their clinical presentation may in fact mimic the more common conditions, such as cholecystitis, choledocholithiasis, cholangiocarcinoma or pancreatic cancer.

Benign neoplasms causing biliary obstruction may be classified as follows:

- papilloma and adenoma
- multiple biliary papillomatosis
- granular cell myoblastoma
- neural tumours
- leiomyoma
- endocrine tumours.

Papilloma and adenoma

The most common benign neoplasms arise from the glandular epithelium lining the bile ducts. They can occur throughout the biliary system, but are more frequent in the periampullary area. Lesions in this area may protrude through the ampulla of Vater and be visible at endoscopy. Jaundice is the most common

symptom occurring in greater than 90 per cent of cases. Coexisting gallstones are uncommon.

Treatment depends on the age, general status of the patient and site of the disease, but in general should consist of total resection of the lesion. In some cases, a wide local resection can be performed.

Papillomatosis

This rare condition is characterised by the presence of multiple mucus-secreting tumours of the biliary epithelium. Patients present with obstructive jaundice which may be intermittent often complicated by cholangitis. These tumours have a malignant potential and should be resected. This may involve liver resection if the disease is confined to a hepatic lobe. If both lobes are affected, then liver transplantation may be required.

Granular cell myoblastoma, neural tumours, leiomyomata and endocrine tumours are extremely uncommon. In general, if biliary obstruction occurs it should be relieved by either biliary resection, bypass or endoscopic stenting.

Malignant tumours of the biliary tract

Malignant tumours of the gall bladder and extrahepatic biliary tree are uncommon. Gall bladder cancer is the predominant type accounting for 60–70 per cent of cases with the remainder distributed between the intra- and extrahepatic biliary tree (Summary box 67.7).

Summary box 67.7

Bile duct cancer (cholangiocarcinoma)

- Rare, but incidence increasing
- Most patients present with abnormal liver function tests or frank jaundice
- Diagnosis by ultrasound, MDR-CT or MRCP scanning
- Majority of patients receive palliative care only
- Complete surgical excision possible in less than 10 per cent
- Prognosis poor – 90 per cent dead in one year from liver failure or biliary sepsis
- Adjuvant chemoradiation therapy has limited role

Unfortunately, due to advanced stage at presentation, surgical resection, which offers the best survival, is only possible in a minority of patients. Thus for most patients treatment is generally palliative in nature and survival limited.

Incidence

Cholangiocarcinoma is a rare malignancy accounting for 1–2 per cent of new cancers in a western practice. The overall annual incidence is 1–1.5 per 100 000 with two-thirds of patients being older than 65 years. It appears to be more common in males with a male:female ratio of approximately 1.5:1.

Anatomically, tumours involving the biliary confluence (hilar cholangiocarcinoma or Klatskin tumours) account for 60 per cent of cases with the remainder in the distal bile duct (20–30 per cent) or intrahepatic (10–20 per cent).

Risk factors

A minority of patients presenting with cholangiocarcinoma are noted to have a known risk factor (Summary box 67.8). The major risk factor in western practice is primary sclerosing

cholangitis (PSC). It is estimated that a long-standing history of PSC increases the risk of developing biliary tract cancer by 20-fold compared to the normal population. It appears that patients with PSC and concomitant inflammatory bowel disease are at significantly higher risk of developing cancer compared to those without the disease. Cholangiocarcinoma appears to occur at an earlier age in patients with PSC (30–50 years of age) compared to the general population. In addition, disease is usually multifocal and detected at advanced stage with resultant poor prognosis.

Summary box 67.8

Risk factors for cholangiocarcinoma

- Chronic inflammatory conditions
 - Primary sclerosing cholangitis
 - Oriental cholangiohepatitis
 - Hepatitis C infection
- Parasitic infections
 - Opisthorchis viverrini*
 - Clonorchis sinensis*
- Congenital
 - Choledochal cysts
 - Caroli's disease
- Chemical agents
 - Thorium dioxide (Thorotrast®)
 - Vinyl chloride
 - Dioxin
 - Asbestos
- Postsurgical
 - Biliary-enteric anastomosis

Congenital cystic disease (Caroli's disease, choledochal cysts), hepatolithiasis, oriental cholangiohepatitis, hepatitis C viral infection and infestation with liver flukes have also been associated with an increased risk of cholangiocarcinoma. Liver fluke infestations are particularly important in South-East Asia. *Opisthorchis viverrini* and *Clonorchis sinensis* infestation is important in Thailand, Laos and western Malaysia. While the pathophysiology is unclear, it is hypothesised that these parasites cause chronic inflammation which leads to DNA changes and mutations through production of carcinogens and free radicals, which stimulate cellular proliferation in the intrahepatic bile ducts and ultimately can lead to invasive cancer.

Other risk factors suggested include chemical carcinogens, such as thorium dioxide, vinyl chloride, dioxin and asbestos.

Clinical features

Early symptoms of cholangiocarcinoma are often non-specific with abdominal pain, early satiety, anorexia and weight loss commonly seen. Symptoms associated with biliary obstruction (pruritus and jaundice) may be present in a minority of patients. In these patients, examination often demonstrates clinical signs of jaundice, cachexia is often noticeable and a palpable gall bladder is present if the obstruction is in the distal common bile duct (Courvoisier's sign).

Investigations

Biochemical investigations will confirm the presence of obstructive jaundice (elevated bilirubin, alkaline phosphatase and

γ -glutamyltransferase). The tumour marker CA 19-9 may also be elevated. Imaging studies, such as ultrasound, multidetector row computed tomography (MDR-CT) and MRI/MRCP, are essential for diagnosis and staging. These studies allow the level of biliary obstruction to be defined and determine the loco-regional extent of disease and the presence of metastases (Figure 67.36).

Direct cholangiography using ERCP or PTC are also used following non-invasive studies. Both can define the level of obstruction and allow access to the biliary system for biopsy and placement of endobiliary stents for biliary drainage. The choice between either modality depends on local availability and the anatomical site of the tumour with PTC preferred for more proximal lesions and ERCP favoured for distal tumours. Cytology can be obtained from either procedure, but it is often non-diagnostic.

Recent work has suggested that combined positron emission tomography (PET) and MDR-CT scanning may be useful in staging cholangiocarcinoma, but further work is required to determine the true value of this modality.

Treatment

A multidisciplinary approach is required in all cases. The choice of treatment depends on the site of the disease and its extent. Unfortunately, the majority of patients present with advanced disease. However, 10–15 per cent are suitable for surgical resection which offers the only hope for long-term survival. The aim of surgical resection is to achieve a complete resection with negative pathological margins and safely restore biliary–enteric continuity. Depending on the site of disease, resections may involve excision of a lobe of the liver and reconstruction of the biliary tree. With the improved techniques associated with hepatic resection, the perioperative mortality rate is now less than 5 per cent. Distal common duct tumours may require a pancreaticoduodenectomy (Whipple procedure).

Liver transplantation has been suggested by some authors for selected patients who have locally unresectable disease

Figure 67.36 A computed tomography scan demonstrating a hilar cholangiocarcinoma (arrowed).

without evidence of distant metastases. Transplantation is often combined with neoadjuvant chemoradiation therapy. While emerging data are encouraging, this aggressive approach remains unproven and is reserved for selected patients in specialised centres.

Following resection, the median survival is approximately 18 months, with 20 per cent of patients surviving five years post-resection. Survival appears better for distal tumours compared to those involving the upper third of the biliary tree. Adjuvant chemotherapy or radiotherapy has a limited role to play and has not been demonstrated to add survival benefit following surgical resection. However, patients at high risk for recurrence (positive surgical margins or node positive) may benefit from adjuvant therapy and should be referred for a medical or radiation oncology opinion.

The majority of patients who present with unresectable disease are candidates for palliative therapy. The aim is to maintain or improve quality of life by relieving symptoms and preventing cholestatic liver failure. Biliary obstruction can be relieved by either endoscopic (ERCP) or percutaneous (PTC) methods. Surgical bypass rarely has a role apart from patients who present with a distal bile duct lesion and are found to have unresectable disease at operation.

Carcinoma of the gall bladder

Incidence

This is a rare disease, but extremely variable by geographical region and racial-ethnic groups. The highest incidence is among Chileans, American Indians and residents in parts of northern India, where it accounts for as much as 9 per cent of all biliary tract disease. Women appear to have a higher incidence across all geographic areas. In western practice, gall bladder cancer accounts for less than 1 per cent of new cancer diagnoses. The disease usually presents in the seventh or eighth decade. The aetiology is unclear, but there appears to be an association with pre-existing gallstone disease suggesting that chronic inflammation may play a role in a manner similar to tumours of the common bile duct. Calcification of the gall bladder wall, presumably due to chronic inflammation (porcelain gall bladder), is also associated with an increased risk of cancer (Figure 67.5). Chronic infection may also promote development of gall bladder cancer and the risk in typhoid carriers is significantly increased over the general population.

Figure 67.37 Ultrasound demonstrating gall bladder polyp. Note lack of acoustic shadow.

Gall bladder polyps may be found in approximately 5 per cent of patients who undergo ultrasonography (Figure 67.37). The majority are either adenomyomatosis or cholesterol polyps and have no malignant potential. True adenomatous polyps do occur and have malignant potential (Summary box 67.9).

Summary box 67.9

Gall bladder cancer

- Very rare
- Similar presentation to benign biliary disease, i.e. gallstones
- Diagnosis by ultrasound, CT scan, MRI/MRCP
- Most patients present with advanced disease
- Surgical resection in less than 10 per cent – remainder receive palliative treatment
- Prognosis is poor – median survival approximately six months

Pathology

The majority (90 per cent) of cases are adenocarcinoma. Squamous carcinomas also occur and are believed to arise from areas of mucosal squamous metaplasia.

At operation, localised carcinomas are difficult to differentiate from chronic cholecystitis; the most commonly presenting tumour is nodular and infiltrative, with thickening of the gall bladder wall, often extending to the whole gall bladder. The tumour spreads by direct extension into the liver, seeding of the peritoneal cavity and involvement of the perihilar lymphatics and neural plexuses. At the time of presentation, the majority of tumours are advanced (Figure 67.38).

Clinical features

Patients may be asymptomatic at the time of diagnosis. Symptoms, if present, are usually indistinguishable from those of benign gall bladder disease, such as biliary colic or cholecystitis, particularly in older patients. Jaundice and anorexia are late features. A palpable mass is a late sign.

Figure 67.38 Laparoscopic staging in a patient with gall bladder carcinoma demonstrating gross peritoneal metastases.

Investigation

Laboratory findings are generally non-specific, but may be consistent with biliary obstruction. Non-specific findings, such as anaemia, leukocytosis, mild elevation in transaminases and increased inflammatory markers, such as ESR or C-reactive protein, may be present. Serum CA19-9 is elevated in approximately 80 per cent of patients.

The preoperative diagnosis is often made on ultrasonography, and confirmed by a MDR-CT scan or MRI/MRCP. Preoperative staging should be aimed at determining the local extent of disease and excluding the presence of distant metastases (Summary box 67.10). A percutaneous biopsy under radiological guidance is often done to obtain tissue for pathological examination. In selected cases, a laparoscopic examination is useful in staging the disease. Laparoscopy can detect peritoneal or liver metastases which would preclude further surgical resection (Figure 67.38).

Summary box 67.10

Aim of staging gall bladder cancer

- Assessment of local disease
- Detection of metastatic disease
 - Liver
 - Peritoneal
 - Lymphatic
 - Extra-abdominal disease

Treatment and prognosis

The majority of patients have advanced disease at presentation, and are not candidates for surgical therapy. Surgery is indicated in only very selected cases.

Cholecystectomy should be performed for all gall bladder polyps greater than 1 cm. Polyps less than 1 cm can be followed with serial ultrasonography to detect any change in size or character as the incidence of malignancy in polyps less than 1 cm is extremely low.

Radical en-bloc resections which may include segmental

or extended hepatectomy, bile duct resection and regional lymphadenectomy should be considered in selected patients. The aim is to remove the tumour entirely and achieve negative histopathological margins.

Patients can have the disease diagnosed following histopathological examination of the gall bladder removed for presumed benign disease. In these cases, the need for further surgery is determined by the stage of disease. For early stage disease confined to the mucosa or muscle of the gall bladder, no further treatment is indicated. However, for transmural disease, a radical en-bloc resection of the gall bladder fossa and surrounding liver along with the regional lymph nodes should be performed. If the initial procedure was performed laparoscopically, the surgeon should examine the laparoscopic port sites. Routine resection of port sites is no longer recommended. However, it is recognised that the finding of disease at the port sites is a sign of generalised peritoneal disease and portends a very poor prognosis.

For the majority of patients, a non-operative approach to palliation is best. Obstructive jaundice can be relieved by endoscopic and/or percutaneous methods. The value of adjuvant therapy is unproven.

Gall bladder cancer for most patients is a lethal disease with a grim prognosis. The median survival is less than six months and a five-year survival figure of 5 per cent reported.

LEARNING OBJECTIVES

To understand:

- The anatomy and physiology of the pancreas
- Investigations of the pancreas

- Congenital abnormalities of the pancreas
- Assessment and management of pancreatitis
- Diagnosis and treatment of pancreatic cancer

ANATOMY AND PHYSIOLOGY

Anatomy

The name 'pancreas' is derived from the Greek 'pan' (all) and 'kreas' (flesh). For a long time, its glandular function was not understood, and it was thought to act as a cushion for the stomach. The pancreas is situated in the retroperitoneum. It is divided into a head, which occupies 30 per cent of the gland by mass, and a body and tail, which together constitute 70 per cent. The head lies within the curve of the duodenum, overlying the body of the second lumbar vertebra and the vena cava. The aorta and the superior mesenteric vessels lie behind the neck of the gland. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pancreas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (Figures 68.1 and 68.2). The tip of the pancreatic tail extends up to the splenic hilum.

The pancreas weighs approximately 80 g. Of this, 80–90 per cent is composed of exocrine acinar tissue, which is organised into lobules. The main pancreatic duct branches into interlobular and intralobular ducts, ductules and, finally, acini. The main duct is lined by columnar epithelium, which becomes cuboidal in the ductules. Acinar cells are clumped around a central lumen, which communicates with the duct system. Clusters of endocrine cells, known as islets of Langerhans, are distributed throughout the pancreas. Islets consist of different cell types: 75 per cent are B cells (producing insulin); 20 per cent are A cells (producing glucagon); and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein, forming a pancreatic portal system.

There are nine key processes that occur during pancreatic embryogenesis (Table 68.1). Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of ductule fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of fetal life, the pancreas differentiates into exocrine and endocrine

Figure 68.1 The posterior relations of the pancreas.

Figure 68.2 Transverse section of the pancreas. Note the position of the uncinate process behind the vessels.

elements. The primitive ducts and their ductules are responsible for the lobular arrangement of the pancreas. Congenital anomalies of the pancreas are varied and arise during the early phase of development (Summary box 68.1). The anatomy of the pancreatic duct is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in Figure 68.3. Approximately 10 per cent of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main duodenal papilla, also known as the ampulla of Vater, is also variable (Figure 68.4). The outlet of each duct is protected by a complex sphincter mechanism (sphincter of Oddi) (Figure 68.5).

Physiology

In response to a meal, the pancreas secretes digestive enzymes in an alkaline (pH 8.4) bicarbonate-rich fluid. Spontaneous secretion is minimal; the hormone secretin, which is released from the duodenal mucosa, evokes a bicarbonate-rich fluid. Cholecystikinin (CCK) (synonym: pancreozymin) is released from the duodenal mucosa in response to food. CCK is responsible for enzyme release. Vagal stimulation increases the volume of secretion. Protein is synthesised at a greater rate (per gram of tissue) in the pancreas than in any other tissue, with the possible exception of the lactating mammary gland. About 90 per cent of this protein is exported from the acinar cells as a variety of digestive enzymes. Approximately 6–20 g of digestive enzymes enter the duodenum each day. Nascent proteins are synthesised as preproteins and undergo modification in a sequence of steps. The proteins move from the rough endothelial endoplasmic reticulum to the Golgi complex, where lysosomes and mature zymogen storage granules containing proteases are stored, and then to the ductal surface of the cell, from which they are extruded by exocytosis. During this phase, the proteolytic enzymes are in an inactive form, the maintenance of which is important in preventing pancreatitis.

INVESTIGATIONS

Estimation of pancreatic enzymes in body fluids

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of serum amylase is the most widely used test of pancreatic damage (serum lipase is more sensitive and specific, but is not widely available). The serum amylase rises within a few hours of pancreatic damage and declines over the next 4–8 days. A markedly elevated serum level is highly suspicious but not diagnostic of acute pancreatitis (Summary box 68.2). Urinary amylase and amylase–creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, computed tomography (CT) of the pancreas is of greater value (Table 68.2).

Summary box 68.2

Causes of raised serum amylase level other than acute pancreatitis

- Upper gastrointestinal tract perforation
- Mesenteric infarction
- Torsion of an intra-abdominal viscus
- Retroperitoneal haematoma
- Ectopic pregnancy
- Macroamylasaemia
- Renal failure
- Salivary gland inflammation

Table 68.2 Investigation of the pancreas.

	Endoscopic retrograde cholangiopancreatography
	Endoscopic ultrasound
Plain radiography	Chest
	Upper abdomen

Pancreatic function tests

Pancreatic exocrine function can be assessed by directly measuring pancreatic secretion in response to a standardised stimulus. The stimulus to secretion can be physiological, e.g. ingestion of a test meal, as in the Lundh test, or pharmacological, e.g. intravenous injection of a hormone, such as secretin or CCK. Duodenal intubation has to be performed with a triple-lumen tube so that the gastric and duodenal juices can be aspirated, and a non-absorbable marker, such as polyethylene glycol, is used to assess the completeness of the aspiration. The nitroblue tetrazolium–*para*-aminobenzoic acid (NBT–PABA) test provides an indirect measure of pancreatic function. The substance is administered orally and degraded in the gut by a pancreatic enzyme, and the breakdown product (PABA) is absorbed by the intestine and excreted in the urine; its urinary level is measured. The Pancreolauryl test works on a similar principle. These tests are cheap and easy to perform, but are non-specific, especially following gastrectomy and in conditions that may alter gastrointestinal transit and intestinal absorptive capacity. Measurement of the enzyme elastase in stool is simple, specific and now used widely. A low level of faecal elastase indicates exocrine insufficiency.

Imaging investigations

Ultrasonography

Ultrasonography is the initial investigation of choice in patients with jaundice to determine whether or not the bile duct is dilated, the coexistence of gallstones or gross disease within

the liver, such as metastases. It may also define the presence or absence of a mass in the pancreas (Figure 68.6). However, obesity and overlying bowel gas often make interpretation of the pancreas itself unsatisfactory.

Computed tomography

Most significant pathologies within the pancreas can be diagnosed on high-quality CT scans, with three-dimensional reconstruction if necessary. A specific pancreatic protocol should be followed. An initial unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gall bladder (Figure 68.7). Then, following rapid injection of intravenous contrast, scanning is performed in the arterial and venous phases. The stomach and duodenum should be outlined with water and distended to define the duodenal loop. Pancreatic carcinomas of 1–2 cm in size can usually be demonstrated whether in the head, body or tail of the pancreas (Figure 68.8). Endocrine tumours are also well imaged on CT (Figure 68.9). In patients with pancreatitis, necrotic areas within the gland can be identified by the absence of contrast enhancement on CT. Inflammatory collections and pseudocysts can be seen (Figure 68.10). CT-guided drainage is helpful in the treatment of pancreatic collections, cysts and pseudocysts, and facilitates percutaneous fine-needle or Trucut biopsy.

Magnetic resonance imaging

With magnetic resonance imaging (MRI), the pancreas can be clearly identified, and the anatomy of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance cholangiography and pancreatography (MRCP) may well replace diagnostic endoscopic retrograde cholangiography and pancreatography (ERCP) as it is non-invasive and less expensive (Figure 68.11). Using the technique in conjunction with intravenous injection of secretin, emptying of the pancreatic duct can be demonstrated to show the absence or presence of obstruction.

Endoscopic retrograde cholangiopancreatography

ERCP is performed using a side-viewing fiberoptic duodenoscope. The ampulla of Vater is intubated, and contrast is

Figure 68.7 (a) Unenhanced computed tomography scan of a man with chronic pancreatitis, showing a focus of calcification (marked by an arrow) in the head of the pancreas and a cyst adjacent to that. Oral contrast has been administered. (b) The same area after injection of intravenous contrast.

Figure 68.8 Contrast-enhanced computed tomography scan of a patient with a carcinoma of the pancreatic head. The main bulk of the tumour lies inferior to the section shown here. The dilated bile duct (1) and main pancreatic duct (2) can be seen, with tumour infiltration around them. There is a thrombus in the superior mesenteric vein (3). The gall bladder is distended (4).

injected into the biliary and pancreatic ducts to display the anatomy radiologically (Figure 68.12). In pancreatic carcinoma, the main pancreatic duct may be narrowed or completely obstructed at the site of the tumour (Figure 68.13), or the distal bile duct may be narrowed. Concurrent narrowing of both ducts results in the so-called double duct sign (Figure 68.14). Changes seen in chronic pancreatitis include the presence of pancreatic duct strictures, dilatation of the main pancreatic duct with stones, abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts, and bile duct strictures (Figures 68.15, 68.16 and 68.17). A plain radiograph before contrast studies is essential to delineate calcification (Figure 68.18). In addition to imaging, bile or pancreatic fluid and brushings from duct strictures can yield cells that confirm the suspected diagnosis of carcinoma (Figure 68.19). Brush cytology taken from malignant strictures at the time of ERCP yields a positive diagnosis in 40–50 per cent of patients. ERCP also allows the placement of biliary and pancreatic stents.

Figure 68.10 Computed tomography scan of a large pseudocyst in relation to the body and tail of the pancreas.

Endoscopic ultrasound

Endoscopic ultrasound (EUS) is performed using a special endoscope that has a high-frequency ultrasonic transducer at its tip. When the endoscope is in the lumen of the stomach or duodenum, the pancreas and its surrounding vasculature and

Figure 68.11 Magnetic resonance cholangiopancreatography in a patient with obstructive jaundice. A dilated common bile duct was seen on ultrasound, but no pancreatic mass lesion was visible on computed tomography. The bile duct and the main pancreatic duct are seen very well, with a stone visible in the lower part of the bile duct and another in the neck of the gall bladder.

Figure 68.13 Endoscopic retrograde cholangiopancreatography: pancreatic carcinoma. Irregular stricture of the main pancreatic duct (marked by an arrow) with dilatation distal to the obstruction.

Figure 68.14 Endoscopic retrograde cholangiopancreatography depicting a malignant stricture in the lower part of the common bile duct (1) and in the main pancreatic duct (2), an appearance referred to as the double duct sign (courtesy of Dr George Webster).

Figure 68.15 Endoscopic retrograde cholangiopancreatography: chronic pancreatitis. Most of the opacities lie within the duct system and are stones. Gross dilatation of ducts in the body and tail are due to obstructions by stones in the head of the pancreas.

Figure 68.16 (a) Endoscopic retrograde cholangiopancreatography: relapsing acute pancreatitis. Normal biliary tree. Pancreatogram shows stricture of the main duct in the body with distal dilatation and cyst formation. (b) Diagrammatic outline of (a). CBD, common bile duct; PD, pancreatic duct.

lymph nodes can be assessed (Figure 68.20). This is particularly useful in identifying small tumours that may not show up well on CT or MRI, and in demonstrating the relationship of a pancreatic tumour to major vessels nearby. EUS can clarify the relationship of a neuroendocrine tumour to the main pancreatic duct (important if enucleation is being considered). It helps to distinguish cystic tumours from pseudocysts. Transduodenal or transgastric fine needle aspiration (FNA) or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity.

CONGENITAL ABNORMALITIES

Cystic fibrosis

This is inherited as an autosomal recessive condition. It occurs most frequently among Caucasians, in whom it is the most common inherited disorder (incidence of 1:2500 live births in the UK). Cystic fibrosis (CF) develops when there is a mutation in the *CFTR* (cystic fibrosis transmembrane conductance regulator) gene on chromosome 7. This gene creates a cell membrane protein that helps to control the movement of chloride across the cell membrane.

CF is a multisystem disorder of exocrine glands that affects the lungs, intestines, pancreas and liver, and is characterised by

elevated sodium and chloride ion concentrations in sweat. The mother may notice that the child is salty when kissed.

Most of the organ damage is due to blockage of narrow passages by thickened secretions. Chronic pulmonary disease arises from plugging of bronchi and bronchioles. CF is the most common cause of chronic lung disease among children in developed countries. Cor pulmonale may develop later. At

birth, the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus) (see Chapter 8). Secretions precipitate in the lumen of the pancreatic duct causing blockage, which results in duct ectasia and fatty replacement of exocrine acinar tissue. Pancreatic exocrine insufficiency leads to fat malabsorption. Steatorrhoea is usually present from birth, resulting in stools that are bulky, oily and offensive. The islets

Figure 68.20 (a) Carcinoma of the pancreatic head as seen on endoscopic ultrasound (EUS). (b) Aspiration biopsy carried out under EUS guidance: needle seen entering the tumour (courtesy of Dr Peter Fairclough).

of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. The liver may become cirrhotic as a result of bile duct plugging, and signs of portal hypertension may appear. Infertility is common, due to the absence of the vas deferens in men and thick cervical mucus in women.

Outside the newborn period, the earliest clinical signs of CF are poor growth, poor appetite, rancid greasy stools, abdominal distension, chronic respiratory disease and finger clubbing. The appearance of secondary sexual characteristics may be delayed. The diagnosis can be made by genetic testing (which may be part of prenatal or newborn screening) and by the sweat test. Levels of sodium and chloride ions in the sweat above 90 mmol/L confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Pulmonary function is preserved with aggressive physiotherapy and antibiotics. Malabsorption is treated by administration of oral pancreatic enzyme preparations. The diet should be low in fat but contain added salt to replace the high losses in the sweat. With early diagnosis and optimal treatment, patients in the western world can now expect to survive to their mid-thirties. Those with end-stage lung disease may be considered for lung transplantation. Heterozygous carriers of the various gene mutations are asymptomatic, but can be identified by DNA analysis. There is a suggestion that such patients may develop pancreatitis later in life.

Pancreas divisum

Pancreas divisum occurs when the embryological ventral and dorsal parts of the pancreas fail to fuse (Figure 68.3). The dorsal pancreatic duct becomes the main pancreatic duct and drains most of the pancreas through the minor or accessory papilla. The incidence of pancreas divisum ranges from 5 per cent in autopsy series to 10 per cent in some ERCP and MRCP series. Pancreas divisum found incidentally in an asymptomatic person does not warrant any intervention. However, the incidence of pancreas divisum ranges from 25 to 50 per cent in patients with recurrent acute pancreatitis, chronic pancreatitis and pancreatic pain. The minor papilla is substantially smaller than the major papilla (and many of these patients probably have papillary stenosis). A large volume of secretions flowing through a narrow papilla probably leads to incomplete drainage, which may then cause obstructive pain or pancreatitis. Certainly in patients with idiopathic recurrent pancreatitis, pancreas divisum should be excluded. The diagnosis can be arrived at by MRCP, EUS or ERCP, augmented by injection of secretin if necessary. There may be changes indicative of obstruction or chronic inflammation in the dorsal duct system. Endoscopic sphincterotomy and stenting of the minor papilla may relieve the symptoms. Surgical intervention can take the form of sphincteroplasty, pancreato-jejunostomy or even resection of the pancreatic head.

Annular pancreas

This is the result of a failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is most often seen in association with congenital duodenal stenosis or atresia and is therefore more prevalent in children with Down's syndrome. Duodenal obstruction typically causes

vomiting in the neonate (see Chapter 8). The usual treatment is bypass (duodenoduodenostomy). The disease may occur in later life as one of the causes of pancreatitis, in which case resection of the head of the pancreas is preferable to lesser procedures.

Ectopic pancreas

Islands of ectopic pancreatic tissue can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel's diverticulum), the gall bladder, adjoining the pancreas, in the hilum of the spleen and within the liver. Ectopic pancreas may also be found in the wall of an alimentary tract duplication cyst (see Chapter 8).

Congenital cystic disease of the pancreas

This sometimes accompanies congenital disease of the kidneys and liver, and occurs as part of the von Hippel-Lindau syndrome.

INJURIES TO THE PANCREAS

External injury

Presentation and management

The pancreas, thanks to its somewhat protected location in the retroperitoneum, is not frequently damaged in blunt abdominal trauma. If there is damage to the pancreas, it is often concomitant with injuries to other viscera, especially the liver, the spleen and the duodenum. Occasionally, a forceful blow to the epigastrium may crush the body of the pancreas against the vertebral column. Penetrating trauma to the upper abdomen or the back carries a higher chance of pancreatic injury. Pancreatic injuries may range from a contusion or laceration of the parenchyma without duct disruption to major parenchymal destruction with duct disruption (sometimes complete transection) and, rarely, massive destruction of the pancreatic head. The most important factor that determines treatment is whether the pancreatic duct has been disrupted.

Blunt pancreatic trauma usually presents with epigastric pain, which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. The clinical presentation can be quite deceptive; careful serial assessments and a high index of suspicion are required. A rise in serum amylase occurs in most cases. A CT scan of the pancreas will delineate the damage that has occurred to the pancreas (Figure 68.21). If there is doubt about duct disruption, an urgent ERCP should be sought. MRCP may also provide the answer, but the images can be difficult to interpret. Support with intravenous fluids and a nil by mouth regimen should be instituted while these investigations are performed. There is no need to rush to a laparotomy if the patient is haemodynamically stable, without peritonitis. It is preferable to manage conservatively at first, investigate and, once the extent of the damage has been ascertained, undertake appropriate action. Operation is indicated if there is disruption of the main pancreatic duct; in almost all other cases, the patient will recover with conservative management. In penetrating injuries, especially if other organs are injured and the patient's condition

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.

Arvid Lindau, 1892–1958, Pathologist, Lund, Sweden, established the link between the retinal angiomas described by von Hippel and the cerebellar and visceral components of the syndrome.

Figure 68.21 Computed tomography scan showing a pancreatic transection due to a bicycle handlebar injury. A distal pancreatectomy was performed.

is unstable, there is a greater need to perform an urgent surgical exploration.

Assessment of pancreatic damage and duct disruption at the time of surgery can be difficult, because the bruising associated with the retroperitoneal damage prevents clear visualisation of the pancreas. A patient and thorough examination of the gland should be carried out. Haemostasis and closed drainage is adequate for minor parenchymal injuries. If the gland is transected in the body or tail, a distal pancreatectomy should be performed, with or without splenectomy. However, if the plane of transection is flat and clean, it may be possible to anastomose the stump of the distal pancreas to a Roux loop of jejunum as an end-to-side pancreatojejunostomy. If damage is purely confined to the head of the pancreas, haemostasis and external drainage is normally effective. In the emergency setting, in an unstable patient with concomitant injuries, a surgeon unaccustomed to pancreatic surgery should refrain from trying to ascertain whether the duct in the pancreatic head is intact or embarking on a major resection. However, if there is severe injury to the pancreatic head and duodenum, then a pancreatoduodenectomy may be necessary (Summary box 68.3).

Summary box 68.3

External injury to the pancreas

- Other organs are likely to be injured
- It is important to ascertain whether the pancreatic duct has been disrupted
- CT and ERCP are the most useful tests
- Surgery is indicated if the main pancreatic duct is disrupted

Prognosis

The most common cause of death in the immediate period is bleeding, usually from associated injuries. Once the acute phase

has passed, the mortality and morbidity related to the pancreatic injury itself are treatable, with a complete return to normal activity the usual outcome.

Persistent drain output occurs in up to a third of patients (see below under Pancreatic fistula). Sometimes, in the aftermath of trauma that has been treated conservatively, duct stricturing develops, leading to recurrent episodes of pancreatitis. The appropriate treatment in such cases is resection of the tail of the pancreas distal to the site of duct disruption.

Also, a pancreatic pseudocyst may develop. If the main duct is intact, the cyst can be aspirated percutaneously in the first instance; it may not be necessary to undertake a cystgastrostomy. If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a cystgastrostomy or even a distal resection or, occasionally, a pancreatojejunostomy with a Roux-en-Y loop. In a patient who presents with a peripancreatic cyst and a history of previous blunt abdominal trauma, do not assume that it is a post-traumatic pseudocyst. The possibility of a cystic neoplasm should be considered and excluded.

Iatrogenic injury

This can occur in several ways:

- Injury to the tail of the pancreas during splenectomy, resulting in a pancreatic fistula.
- Injury to the accessory pancreatic duct (Santorini), which is the main duct in 7 per cent of patients, during Billroth II gastrectomy. A pancreatogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated, then the duct should be reanastomosed to the duodenum.
- Enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

Pancreatic fistula

Pancreatic fistula usually follows operative trauma to the gland or occurs as a complication of acute or chronic pancreatitis. It is important to define the site of the fistula and the epithelial structure with which it communicates (e.g. externally to skin or internally to bowel). If there is uncertainty about whether the fluid issuing from a drain site or a wound is pancreatic, measurement of the amylase content will be diagnostic.

Management includes correction of metabolic and electrolyte disturbances and adequate drainage of the fistula into a stoma bag with protection of the skin. Investigation of the cause of the fistula is required as the underlying cause must be treated before the fistula will close. Frequently, the cause is related to obstruction within the pancreatic duct, which can be overcome by the insertion of a stent or catheter endoscopically into the pancreatic duct. While waiting for closure of the fistula, the patient should be given parenteral or nasojejunal nutritional support (as opposed to nasogastric or oral feeding; the rationale is that parenteral or nasojejunal feeding reduces the volume of pancreatic secretion). The use of octreotide will also suppress pancreatic secretion (Summary box 68.4) (see also Chapter 20).

Giovanni Domenico Santorini, 1681–1737, Professor of Anatomy and Medicine, Venice, Italy. His drawings of the accessory pancreatic duct were published after his death.

Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria. A hugely influential surgical teacher and an early proponent of surgical audit, Billroth performed the first oesophagectomy, first laryngectomy and first successful gastrectomy. He was also a talented musician and a friend of the composer Brahms.

Summary box 68.4

Management of pancreatic fistulae

- Tests
 - Measure amylase level in fluid
 - Determine the anatomy of the fistula
 - Check whether the main pancreatic duct is blocked or disrupted
- Measures
 - Correct fluid and electrolyte imbalances
 - Protect the skin
 - Drain adequately
 - Parenteral or nasojejunal feeding
 - Octreotide to suppress secretion
 - Relieve pancreatic duct obstruction if possible (ERCP and stent)
 - Treat underlying cause

PANCREATITIS

Pancreatitis is inflammation of the gland parenchyma of the pancreas. For clinical purposes, it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic, which is a prolonged and frequently lifelong disorder resulting from the development of fibrosis within the pancreas. It is probable that acute pancreatitis is but a phase of chronic pancreatitis.

Acute pancreatitis is defined as an acute condition presenting with abdominal pain and is usually associated with raised pancreatic enzyme levels in the blood or urine as a result of pancreatic inflammation. Acute pancreatitis may recur.

The underlying mechanism of injury in pancreatitis is thought to be premature activation of pancreatic enzymes within the pancreas, leading to a process of autodigestion. Anything that injures the acinar cell and impairs the secretion of zymogen granules, or damages the duct epithelium and thus delays enzymatic secretion, can trigger acute pancreatitis. Once cellular injury has been initiated, the inflammatory process can lead to pancreatic oedema, haemorrhage and, eventually, necrosis. As inflammatory mediators are released into the circulation, systemic complications can arise, such as haemodynamic instability, bacteraemia (due to translocation of gut flora), acute respiratory distress syndrome and pleural effusions, gastrointestinal haemorrhage, renal failure and disseminated intravascular coagulation (DIC).

Acute pancreatitis may be categorised as mild or severe. **Mild acute pancreatitis** is characterised by interstitial oedema of the gland and minimal organ dysfunction. Eighty per cent of patients will have a mild attack of pancreatitis, the mortality from which is around 1 per cent. **Severe acute pancreatitis** is characterised by pancreatic necrosis, a severe systemic inflammatory response and often multi-organ failure. In those who have a severe attack of pancreatitis, the mortality varies from 20 to 50 per cent. About one-third of deaths occur in the early phase of the attack, from multiple organ failure, while deaths occurring after the first week of onset are due to septic complications.

Chronic pancreatitis is defined as a continuing inflammatory disease of the pancreas characterised by irreversible morphological change typically causing pain and/or permanent loss of function. Many patients with chronic pancreatitis have painful exacerbations, but the condition may be completely painless.

Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3 per cent of all cases of abdominal pain among patients admitted to hospital in the UK. The hospital admission rate for acute pancreatitis is 9.8 per year per 100 000 population in the UK, although worldwide, the annual incidence may range from 5 to 50 per 100 000. The disease may occur at any age, with a peak in young men and older women.

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occur in 50–70 per cent of patients, and alcohol abuse, which accounts for 25 per cent of cases. Gallstone pancreatitis is thought to be triggered by the passage of gallstones down the common bile duct. If the biliary and pancreatic ducts join to share a common channel before ending at the ampulla, then obstruction of this passage may lead to reflux of bile or activated pancreatic enzymes into the pancreatic duct. Patients who have small gallstones and a wide cystic duct may be at a higher risk of passing stones. The proposed mechanisms for alcoholic pancreatitis include the effects of diet, malnutrition, direct toxicity of alcohol, concomitant tobacco smoking, hypersecretion, duct obstruction or reflux, and hyperlipidaemia. The remaining cases may be due to rare causes or be idiopathic (Summary box 68.5).

Summary box 68.5

Possible causes of acute pancreatitis

- Gallstones
- Alcoholism
- Post-ERCP
- Abdominal trauma
- Following biliary, upper gastrointestinal or cardiothoracic surgery
- Ampullary tumour
- Drugs (corticosteroids, azathioprine, asparaginase, valproic acid, thiazides, oestrogens)
- Hyperparathyroidism
- Hypercalcaemia
- Pancreas divisum
- Autoimmune pancreatitis
- Hereditary pancreatitis
- Viral infections (mumps, Coxsackie B)
- Malnutrition
- Scorpion bite
- Idiopathic

Among patients who undergo ERCP, 1–3 per cent develop pancreatitis, probably as a consequence of duct disruption and enzyme extravasation. Patients with sphincter of Oddi dysfunction or a history of recurrent pancreatitis, and those who undergo sphincterotomy or balloon dilatation of the sphincter, carry a higher risk of developing post-ERCP pancreatitis. Patients who have undergone upper abdominal or cardiothoracic surgery may develop acute pancreatitis in the postoperative phase, as may those who have suffered blunt abdominal trauma.

Hereditary pancreatitis is a rare familial condition associated with mutations of the cationic trypsinogen gene. Patients have a tendency to suffer acute pancreatitis while in their teens, progress to chronic pancreatitis in the next two decades and

have a high risk (possibly up to 40 per cent) of developing pancreatic cancer by the age of 70 years.

Occasionally, tumours at the ampulla of Vater may cause acute pancreatitis. It is important to check the serum calcium level, a fasting lipid profile, autoimmune markers and viral titres in patients with so-called idiopathic acute pancreatitis. It is equally important to take a detailed drug history and remember the association of corticosteroids, azathioprine, asparaginase and valproic acid with acute pancreatitis. A careful search for the aetiology must be made in all cases, and no more than 20 per cent of cases should fall into the idiopathic category (Summary box 68.6).

Summary box 68.6

Aetiology of acute pancreatitis

- It is essential to establish the aetiology
- Investigate thoroughly before labelling it as 'idiopathic'
- After the acute episode resolves, remember further management of the underlying aetiology
- If the aetiology is gallstones, cholecystectomy is desirable during the same admission

Clinical presentation

Pain is the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours and persists for hours or even days. The pain is frequently severe, constant and refractory to the usual doses of analgesics. Pain is usually experienced first in the epigastrium but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50 per cent of patients, and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis.

Nausea, repeated vomiting and retching are usually marked accompaniments. The retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination, the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity and confusion. Tachypnoea is common, tachycardia is usual, and hypotension may be present. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. Mild icterus can be caused by biliary obstruction in gallstone pancreatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce bluish discolouration of the flanks (Grey Turner's sign) or umbilicus (Cullen's sign). Neither sign is pathogno-

monic of acute pancreatitis; Cullen's sign was first described in association with rupture of an ectopic pregnancy. Subcutaneous fat necrosis may produce small, red, tender nodules on the skin of the legs.

Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in the epigastrium due to inflammation. There is usually muscle guarding in the upper abdomen, although marked rigidity is unusual. A pleural effusion is present in 10–20 per cent of patients. Pulmonary oedema and pneumonitis are also described and may give rise to the differential diagnosis of pneumonia or myocardial infarction. The patient may be confused and exhibit the signs of metabolic derangement together with hypoxaemia.

Investigations

Typically, the diagnosis is made on the basis of the clinical presentation and an elevated serum amylase level. A serum amylase level three to four times above normal is indicative of the disease. A normal serum amylase level does not exclude acute pancreatitis, particularly if the patient has presented a few days later. If the serum lipase level can be checked, it provides a slightly more sensitive and specific test than amylase. If there is doubt, and other causes of acute abdomen have to be excluded, contrast-enhanced CT is probably the best single imaging investigation (see below under Imaging) (Summary box 68.7).

Summary box 68.7

Investigations in acute pancreatitis should be aimed at answering three questions:

- Is a diagnosis of acute pancreatitis correct?
- How severe is the attack?
- What is the aetiology?

Assessment of severity

On account of the difference in outcome between patients with mild and severe disease, it is important to define that group of patients who will develop severe pancreatitis. Various scoring systems have been introduced, such as the Ranson and Glasgow scoring systems (Table 68.3). The APACHE II scoring system, used in intensive care units, can also be applied. A severe attack may be heralded by an initial clinical impression of a very ill patient and an APACHE II score above 8. At 48 hours after the onset of symptoms, a Glasgow score of 3 or more, a C-reactive protein level greater than 150 mg/L and a worsening clinical state with sepsis or persisting organ failure indicate a severe attack. Severity stratification should be performed in all patients within 48 hours of diagnosis. Patients with a body mass index over 30 are at higher risk of developing complications.

Imaging

Plain erect chest and abdominal radiographs are not diagnostic of acute pancreatitis, but are useful in the differential diagnosis. Non-specific findings in pancreatitis include a generalised or local ileus (sentinel loop), a colon cut-off sign and a renal halo

George Grey Turner, 1877–1951, Professor of Surgery, The University of Durham, Durham (1927–1934), and at the Postgraduate Medical School, Hammersmith, London, UK (1934–1945). The Grey Turner Travelling Surgical Club was named after him.

Thomas Stephen Cullen, 1868–1953, Professor of Gynecology, The Johns Hopkins University, Baltimore, MD, USA. Described bluish discolouration of the periumbilical skin as a sign of ruptured ectopic pregnancy.

John HC Ranson, 1938–1995, Professor of Surgery, The New York University School of Medicine, New York, NY, USA, was born in India, trained at St Bartholomew's Hospital, London, UK. Described his criteria for severity of acute pancreatitis in 1974.

Table 68.3 Scoring systems to predict the severity of acute pancreatitis: in both systems, disease is classified as severe when three or more factors are present.

Ranson score	Glasgow scale
On admission	On admission
Age >55 years	Age >55 years
White blood cell count $>16 \times 10^9/L$	White blood cell count $>15 \times 10^9/L$
Blood glucose >10 mmol/L	Blood glucose >10 mmol/L (no history of diabetes)
LDH >700 units/L	Serum urea >16 mmol/L (no response to intravenous fluids)
AST >250 Sigma Frankel units per cent	Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)
Within 48 hours	Within 48 hours
Blood urea nitrogen rise >5 mg per cent	Serum calcium <2.0 mmol/L
Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)	Serum albumin <32 g/L
Serum calcium <2.0 mmol/L	LDH >600 units/L
Base deficit >4 mmol/L	AST/ALT >600 units/L
Fluid sequestration >6 litres	

ALT, alanine aminotransferase; AST, aspartate aminotransferase; LDH, lactate dehydrogenase; PaO_2 , arterial oxygen tension.

sign. Occasionally, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show a pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing may suggest acute respiratory distress syndrome.

Ultrasound does not establish a diagnosis of acute pancreatitis. The swollen pancreas may be seen, but ultrasonography should be performed within 24 hours in all patients to detect gallstones as a potential cause, rule out acute cholecystitis as a differential diagnosis and determine whether the common bile duct is dilated.

CT is not necessary for all patients, particularly those deemed to have a mild attack on prognostic criteria. However, a contrast-enhanced CT is indicated in the following situations:

- if there is diagnostic uncertainty;
- in patients with severe acute pancreatitis, to distinguish interstitial from necrotising pancreatitis (Figure 68.22). In the first 72 hours, CT may underestimate the extent of necrosis. The severity of pancreatitis detected on CT may be staged according to the Balthazar criteria;
- in patients with organ failure, signs of sepsis or progressive clinical deterioration;
- when a localised complication is suspected, such as fluid collection, pseudocyst or a pseudoaneurysm.

Cross-sectional MRI can yield similar information to that obtained by CT. EUS and MRCP can help in detecting stones in the common bile duct and directly assessing the pancreatic parenchyma, but are not widely available. ERCP allows the identification and removal of stones in the common bile duct in gallstone pancreatitis. In patients with severe acute gallstone pancreatitis and signs of ongoing biliary obstruction and cholangitis, an urgent ERCP should be sought (see below under Management).

The presentation is so variable that sometimes even an experienced clinician can be mistaken. While this is not desirable, occasionally the diagnosis is only made at laparotomy. The appearances at laparotomy are characteristic (Figure 68.23).

Management

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with intravenous fluid administration and frequent, but non-invasive, observation. A brief period of fasting may be sensible in a

Figure 68.22 Contrast-enhanced computed tomography scan showing acute necrotising pancreatitis. Note the area of reduced enhancement in the pancreas (marked X), the peripancreatic oedema and stranding of the fatty tissues (courtesy of Dr Niall Power).

Emil J Balthazar, contemporary, Professor Emeritus, The Department of Radiology, The New York University, New York, NY, USA.

Figure 68.23 Widespread fat necrosis of the omentum. A test tube has been filled with blood-stained peritoneal fluid. This specimen was rich in amylase. Fat necroses are dull, opaque, yellow-white areas suggestive of drops of wax. They are most abundant in the vicinity of the pancreas, but are widespread in the greater omentum and the mesentery. At necropsy, they can sometimes be demonstrated beneath the pleura and pericardium, and even in the subsynovial fat of the knee joint. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps (fatty necrosis) (courtesy of Dr GD Adhia, Mumbai, India).

patient who is nauseated and in pain, but there is little physiological justification for keeping patients on a prolonged 'nil by mouth' regimen. Antibiotics are not indicated. Apart from analgesics and anti-emetics, no drugs or interventions are warranted, and CT scanning is unnecessary unless there is evidence of deterioration. However, if a stable patient meets the prognostic criteria for a severe attack of pancreatitis, then a more aggressive approach is required, with the patient being admitted to a high-dependency or an intensive care unit and monitored invasively.

Patients with a severe attack should be admitted to an intensive care or high-dependency unit (Table 68.4). Adequate analgesia should be administered. Aggressive fluid resuscitation is important, guided by frequent measurement of vital signs, urine output and central venous pressure. Supplemental oxygen should be administered and serial arterial blood gas analysis performed. The haematocrit, clotting profile, blood glucose and serum levels of calcium and magnesium should be closely monitored.

A nasogastric tube is not essential but may be of value in patients with vomiting. Specific treatments, such as aprotinin, somatostatin analogues, platelet-activating factor inhibitors and selective gut decontamination, have failed to improve outcome in numerous clinical trials and should not be given. There are no data to support a practice of 'resting' the pancreas and feeding only by the parenteral or nasojejunal routes. If nutritional support is felt to be necessary, enteral nutrition (e.g. feeding via a nasogastric tube) should be used.

There is some evidence to support the use of prophylactic antibiotics in patients with severe acute pancreatitis, but there is no consensus. The rationale is to prevent local and other septic

Table 68.4 Early management of severe acute pancreatitis.

Admission to HDU/ICU
Analgesia
Aggressive fluid rehydration
Oxygenation
Invasive monitoring of vital signs, central venous pressure, urine output, blood gases
Frequent monitoring of haematological and biochemical parameters (including liver and renal function, clotting, serum calcium, blood glucose)
Nasogastric drainage
Antibiotic prophylaxis can be considered (imipenem, cefuroxime)
CT scan essential if organ failure, clinical deterioration or signs of sepsis develop
ERCP within 72 hours for severe gallstone pancreatitis or signs of cholangitis
Supportive therapy for organ failure if it develops (inotropes, ventilatory support, haemofiltration, etc.)
If nutritional support is required, consider enteral (nasogastric) feeding

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; HDU, high-dependency unit; ICU, intensive care unit.

complications. The regimens used include intravenous cefuroxime, or imipenem, or ciprofloxacin plus metronidazole. The duration of antibiotic prophylaxis should not exceed 14 days. Additional antibiotic use should be guided by microbiological cultures.

If gallstones are the cause of an attack of predicted or proven severe pancreatitis, or if the patient has jaundice, cholangitis or a dilated common bile duct, urgent ERCP should be carried out within 72 hours of the onset of symptoms. There is evidence that sphincterotomy and clearance of the bile duct can reduce the incidence of infective complications in these patients. In patients with cholangitis, sphincterotomy should be carried out or a biliary stent placed to drain the duct. ERCP is an invasive procedure and carries a small risk of worsening the pancreatitis.

Systemic complications

Pancreatitis may involve all organ systems (Table 68.5) and place demands on the surgeon beyond his or her skills. Patients with systemic complications should be managed by a multidisciplinary team that includes intensive care specialists. When there is organ failure, appropriate supportive therapies may include inotropic support for haemodynamic instability, haemofiltration in the event of renal failure, ventilatory support for respiratory failure and correction of coagulopathies (including DIC). There is no role for surgery during the initial period of resuscitation and stabilisation; surgical intervention is contemplated only in the patient who deteriorates as a result of local complications following successful stabilisation.

Local complications and their management

Once the acute phase has been survived, usually by the end of

Table 68.5 Complications of acute pancreatitis.

Systemic	Local
<i>(More common in the first week)</i>	<i>(Usually develop after the first week)</i>
Cardiovascular	Acute fluid collection
Shock	Sterile pancreatic necrosis

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

the first week, and major organ failure is under control, then local complications become pre-eminent in the management of these patients. The course of the patient should be followed carefully and, if clinical resolution does not take place or signs of sepsis develop, a CT scan should be performed. It is important to be clear about the definitions. Certain terms are confusing, such as 'phlegmon', which may refer to an abscess or to an inflammatory mass in the pancreas. Local complications in pancreatic disease are serious and carry a significant mortality. The management approach is conservative on the whole, with surgery restricted to situations in which conservative management has failed.

Acute fluid collection

This occurs early in the course of acute pancreatitis and is located in or near the pancreas. The wall encompassing the collection is ill defined. The fluid is sterile and most such collections resolve. No intervention is necessary unless a large collection causes symptoms or pressure effects, in which case it can be percutaneously aspirated under ultrasound or CT guidance. Transgastric drainage under EUS guidance is another option. An acute fluid collection that does not resolve can evolve into a pseudocyst or an abscess if it becomes infected.

Sterile and infected pancreatic necrosis

The term 'pancreatic necrosis' refers to a diffuse or focal area of non-viable parenchyma that is typically associated with peripancreatic fat necrosis. Necrotic areas can be identified by an absence of contrast enhancement on CT. These are sterile to begin with, but can become subsequently infected, probably due to translocation of gut bacteria. Infected necrosis is

Figure 68.24 Infected pancreatic necrosis in an elderly patient. Note the areas of reduced enhancement in the pancreas and the peripancreatic fluid collection with pockets of gas within it (arrow). This resolved after percutaneous drainage and antibiotic therapy.

associated with a mortality rate of up to 50 per cent. Sterile necrotic material should not be drained or interfered with. However, if the patient shows signs of sepsis, then one should determine whether the necrotic pancreas or the peripancreatic fluid is infected (Figure 68.24). A CT scan should be performed and a needle passed into the area under CT guidance, choosing a path that does not traverse hollow viscera. This may be done under ultrasonographic guidance as well. If the aspirate is purulent, percutaneous drainage of the infected fluid should be carried out. The tube drain inserted should have the widest bore possible. The aspirate should be sent for microbiological assessment, and appropriate antibiotic therapy should be commenced as per the sensitivity report. The fluid can be quite viscous with particulate matter, and the drain may need regular flushing with full aseptic precautions. Often, repeated imaging and repeated insertion of drains is necessary.

If the sepsis worsens despite this, then a pancreatic necrosectomy should be considered. This is a challenging operation that carries a high morbidity and mortality, and is best carried out in a specialist unit. The overwhelming majority of patients with peripancreatic sepsis can be successfully treated by conservative means, and necrosectomy should be necessary in a very small proportion of patients. The surgical approach may be through a mid-line laparotomy, especially if the area involved is around the head of the gland. The duodenocolic and gastrocolic ligaments should be divided and the lesser sac opened. Thorough debridement of the dead tissue around the pancreas should be carried out. If the body and tail of the gland are primarily involved (Figure 68.25), a retroperitoneal approach through a left flank incision may be more appropriate. The tissues are inevitably friable, and one should be careful not to precipitate excessive bleeding or inadvertently breach the bowel wall. Blunt dissection is preferable to sharp dissection. A feeding jejunostomy may be a useful adjunct to the procedure. If gallstones are the precipitating factor of the pancreatitis, a cholecystectomy should be included. Some prefer a minimally invasive approach to a formal laparotomy. A rigid laparoscope is inserted into the peripancreatic area through a retroperitoneal approach, and vigorous

Figure 68.25 Necrotic body and tail of the pancreas removed as an intact specimen rather than piecemeal. The patient had suffered severe necrotising gallstone pancreatitis complicated by persistent pancreatic sepsis. Necrosectomy was carried out through a left flank retroperitoneal approach.

irrigation and suction is combined with a gradual nibbling away of the necrotic debris.

Once a necrosectomy has been completed, further necrotic tissue may form. There are several possible ways of dealing with this (listed below), none of which has been proved to be more effective than the others. The last two approaches make greater logistic demands as one is committed to a re-exploration every 48–72 hours.

- **Closed continuous lavage.** Tube drains are left in and the raw area flushed (Beger) (Figure 68.26).
- **Closed drainage.** The incision is closed, but the cavity is packed with gauze-filled Penrose drains and closed suction drains. The Penrose drains are brought out through the flank and slowly pulled out and removed after 7 days.
- **Open packing.** The incision is left open and the cavity is packed with the intention of returning to the operating theatre at regular intervals and repacking until there is a clean granulating cavity.

Figure 68.26 Continuous postoperative closed lavage of the lesser sac as advised by Beger. Lavage is carried out through several double-lumen and single-lumen catheters. Each time, 1 litre of saline is infused through and then drained over a period of hours, and the process is repeated.

- **Closure and relaparotomy.** The incision is closed with drains with the intention of performing a series of planned relaparotomies every 48–72 hours until the raw area granulates (Bradley).

There is a subgroup of patients who respond initially to percutaneous treatment but then develop recurrent sepsis that requires repeated insertion of drains, and fail to thrive. Necrosectomy should be considered in these patients, but it can be a difficult judgement call.

Patients with peripancreatic sepsis are ill for long periods of time, and may require management in an intensive care unit. Nutritional support is essential. The parenteral and nasojejunal approaches are more popular (on the assumption that they rest the pancreas), although there is little evidence to show that nasogastric feeding, if tolerated, is harmful in any way.

Pancreatic abscess

This is a circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas. It may be an acute fluid collection or a pseudocyst that has become infected. The principles of diagnosis and management are as outlined above for infected pancreatic necrosis. Percutaneous drainage with the widest possible drains placed under imaging guidance is the treatment, along with appropriate antibiotics and supportive care. Repeated scans may be required depending on the progress of the patient, and drains may need to be flushed, repositioned or reinserted. Very occasionally, open drainage of the abscess may be necessary.

Pancreatic ascites

This is a chronic, generalised, peritoneal, enzyme-rich effusion usually associated with pancreatic duct disruption. Paracentesis will reveal turbid fluid with a high amylase level. Adequate drainage with wide-bore drains placed under imaging guidance is essential. Measures that can be taken to suppress pancreatic secretion include parenteral or nasojejunal feeding and administration of octreotide. An ERCP may allow demonstration of the duct disruption and placement of a pancreatic stent.

Pancreatic effusion

This is an encapsulated collection of fluid in the pleural cavity, arising as a consequence of acute pancreatitis. Concomitant pancreatic ascites may be present, or there may be a communication with an intra-abdominal collection. Percutaneous drainage under imaging guidance is necessary.

Haemorrhage

Bleeding may occur into the gut, into the retroperitoneum or into the peritoneal cavity. Possible causes include bleeding into a pseudocyst cavity, diffuse bleeding from a large raw surface, or a pseudoaneurysm. The last is a false aneurysm of a major peripancreatic vessel confined as a clot by the surrounding tissues and often associated with infection. Recurrent bleeding is common, often culminating in fatal haemorrhage. CT, angiography or magnetic resonance angiography (MRA) helps to make the diagnosis. Treatment involves embolisation or surgery.

Portal or splenic vein thrombosis

This may often develop silently and is identified on a CT scan. A marked rise in the platelet count should raise suspicions. In

the context of acute pancreatitis, treatment is usually conservative. The patient should be screened for pro-coagulant tendencies. If varices or other manifestations of portal hypertension develop, they will require treatment, such as endoscopic injection or banding, β -blockade, etc. Thrombocytosis may mandate the use of aspirin or other anti-platelet drugs for a period. Systemic anticoagulation, if instituted early in the process, may achieve recanalisation of the vein, but it is not routinely used as it carries considerable risks in a patient with ongoing pancreatitis.

Pseudocyst

A pseudocyst is a collection of amylase-rich fluid enclosed in a wall of fibrous or granulation tissue. Pseudocysts typically arise following an attack of acute pancreatitis, but can develop in chronic pancreatitis or after pancreatic trauma. Formation of a pseudocyst requires 4 weeks or more from the onset of acute pancreatitis (Figure 68.27; see also Figure 68.10). They are often single but, occasionally, patients will develop multiple pseudocysts. If carefully investigated, more than half will be found to have a communication with the main pancreatic duct.

A pseudocyst is usually identified on ultrasound or a CT scan. It is important to differentiate a pseudocyst from an acute fluid collection or an abscess; the clinical scenario and the radiological appearances should allow that distinction to be made. Occasionally, a cystic neoplasm may be confused with a chronic pseudocyst. EUS and aspiration of the cyst fluid is very useful in such a situation. The fluid should be sent for measurement of carcinoembryonic antigen (CEA) levels, amylase levels and cytology. Fluid from a pseudocyst typically has a low CEA level, and levels above 400 ng/mL are suggestive of a mucinous neoplasm. Pseudocyst fluid usually has a high amylase level, but that is not diagnostic, as a tumour that communicates with the duct system may yield similar findings. Cytology typically reveals inflammatory cells in pseudocyst fluid. If there is no access to EUS, then percutaneous FNA is acceptable (just aspiration, not percutaneous insertion of a drain). ERCP and MRCP may demonstrate communication of the cyst with the pancreatic

duct system, demonstrate ductal anomalies or diagnose chronic pancreatitis and thus help in planning treatment.

Pseudocysts will resolve spontaneously in most instances, but complications can develop (Table 68.6). Pseudocysts that are thick-walled or large (over 6 cm in diameter), have lasted for a long time (over 12 weeks) or have arisen in the context of chronic pancreatitis are less likely to resolve spontaneously, but these factors are not specific indications for intervention. Therapeutic interventions are advised only if the pseudocyst causes symptoms, if complications develop or a distinction has to be made between a pseudocyst and a tumour.

There are three possible approaches to draining a pseudocyst: percutaneous, endoscopic and surgical. Percutaneous drainage to the exterior under radiological guidance should be avoided. It carries a very high likelihood of recurrence. Moreover, it is not advisable unless one is absolutely certain that the cyst is not neoplastic and that it has no communication with the pancreatic duct (or else a pancreaticocutaneous fistula will develop). A percutaneous transgastric cystgastrostomy can be done under imaging guidance, and a double-pigtail drain placed with one end in the cyst cavity and the other end in the gastric lumen. This requires specialist expertise but, in experienced hands, the recurrence rates are no more than 15 per cent. Endoscopic drainage usually involves puncture of the cyst through the stomach or duodenal wall under EUS guidance, and placement of a tube drain with one end in the cyst cavity and the other end in the gastric lumen. The success rates depend on operator expertise. Occasionally, ERCP and placement of a pancreatic stent across the ampulla may help to drain a pseudocyst that is in communication with the duct. Surgical drainage involves internally draining the cyst into the gastric or jejunal lumen (Figure 68.28). Recurrence rates should be no more than 5 per cent, and this still remains the standard against which the evolving radiological and endoscopic approaches are measured. The approach is conventionally through an open incision, but laparoscopic cystgastrostomy is also feasible. Pseudocysts that have developed complications are best managed surgically (Summary box 68.8).

Figure 68.27 Barium meal. Pseudocyst displacing the stomach (courtesy of Professor VK Kapoor, Lucknow, India).

Table 68.6 Possible complications of a pancreatic pseudocyst.

Process	Outcomes
Infection	Abscess Systemic sepsis
Rupture

Figure 68.28 Cystgastrostomy for the pancreatic pseudocyst shown in Figure 68.10. The anterior wall of the stomach has been opened and the edges drawn back, held by Babcock's forceps. An opening has been made through the posterior wall of the stomach into the pseudocyst, and the tips of the dissecting forceps are in the cavity of the pseudocyst, which is lined by slough and granulation tissue. The tip of a nasogastric tube is visible. A running stitch will next be placed along the edges of this opening, suturing the full thickness of the posterior gastric wall to the capsule of the pseudocyst.

Summary box 68.8

Distinguishing a pseudocyst from a cystic neoplasm

- History
- Appearance on CT and ultrasound
- FNA of fluid, preferably under EUS guidance
 - CEA (high level in mucinous tumours)
 - Amylase (level usually high in pseudocysts, but occasionally in tumours)
 - Cytology

Outcomes and follow up of acute pancreatitis

The overall mortality from acute pancreatitis has remained at 10–15 per cent over the past 20 years. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis, and the causes listed in Summary box 68.5 must be looked for and excluded. Failure to remove a predisposing factor could lead to a second attack of pancreatitis, which could be fatal. A proportion of patients in the idiopathic group who suffer repeated attacks may prove to have biliary microlithiasis, which can be identified only by bile sampling at ERCP or by endoscopic ultrasound. In a patient who has gallstone pancreatitis, the gallbladder and gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Chronic pancreatitis

Chronic pancreatitis is a progressive inflammatory disease in which there is irreversible destruction of pancreatic tissue. Its clinical course is characterised by severe pain and, in the

later stages, exocrine and endocrine pancreatic insufficiency. In the early stages of its evolution, it is frequently complicated by attacks of acute pancreatitis, which are responsible for the recurrent pain that may be the only clinical symptom. The incidence of chronic pancreatitis in several European, North American and Japanese studies ranges from two to ten new cases per 100 000 population per year, with a prevalence of around 13 cases per 100 000, although there are suspicions that the prevalence is actually higher. In certain parts of the world, such as southern India, the prevalence is much higher (100–200 per 100 000). The disease occurs more frequently in men (male to female ratio of 4:1), and the mean age of onset is about 40 years.

Aetiology and pathology

High alcohol consumption is the most frequent cause of chronic pancreatitis, accounting for 60–70 per cent of cases, but only 5–10 per cent of people with alcoholism develop chronic pancreatitis. The exact mechanism of how alcohol causes chronic inflammation in these patients is unclear; genetic and metabolic factors may be at play.

Other causes include pancreatic duct obstruction resulting from stricture formation after trauma, after acute pancreatitis or even occlusion of the duct by pancreatic cancer. Congenital abnormalities, such as pancreas divisum and annular pancreas, if associated with papillary stenosis, are rare causes of chronic pancreatitis.

Hereditary pancreatitis, CF, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Normally, if trypsinogen does become prematurely activated within the pancreas, it is inhibited by *SPINK1* and then gets destroyed. Hereditary pancreatitis is an autosomal dominant disorder with an 80 per cent penetrance, associated with a gain-of-function mutation in the cationic trypsinogen gene (*PRSS1*) on chromosome 7, which leads to production of a degradation-resistant form of trypsin. A loss-of-function mutation in *SPINK1* also predisposes to idiopathic pancreatitis. Some patients with idiopathic chronic pancreatitis have mutations in the *CFTR* gene. Idiopathic chronic pancreatitis accounts for approximately 30 per cent of cases and has been subdivided into early-onset and late-onset forms.

Tropical pancreatitis is a form of idiopathic pancreatitis that begins at a young age and is associated with a high incidence of diabetes mellitus and stone formation. This has been described in Kerala, in southern India, as well as in other developing countries in Asia, Africa and central America. Malnutrition, ingestion of cyanogenic glycosides in cassava, and exposure to hydrocarbons released by kerosene or paraffin lamps have been proposed as possible mechanisms for tropical pancreatitis. The importance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is a markedly increased risk of developing pancreatic cancer, particularly if the patient smokes tobacco. Hyperlipidaemia and hypercalcaemia can lead to chronic pancreatitis.

Autoimmune pancreatitis has been described relatively recently. Features include diffuse enlargement of the pancreas, diffuse and irregular narrowing of the main pancreatic duct. It may occur in association with other autoimmune diseases, as a multi-system disorder, or may affect the pancreas alone. The changes may be confused with neoplasia. Autoantibodies may be present and levels of the immunoglobulin subtype IgG4 are elevated.

At the onset of the disease when symptoms have developed, the pancreas may appear normal. Later, the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris, and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

Clinical features

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas, then epigastric and right subcostal pain is common, whereas if it is limited to the left side of the pancreas, left subcostal and back pain are the presenting symptoms. In some patients, the pain is more diffuse. Radiation to the shoulder, usually the left shoulder, occurs. Nausea is common during attacks and vomiting may occur. The pain is often dull and gnawing. Severe flare up of pain may occur superimposed on background discomfort. All the complications of acute pancreatitis can occur with chronic pancreatitis. Weight loss is common, because the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use and abuse is frequent. This, too, gives an indication of the severity of the disability. The patient's lifestyle is gradually destroyed by pain, analgesic dependence, weight loss and inability to work. Loss of exocrine function leads to steatorrhoea in more than 30 per cent of patients with chronic pancreatitis. Loss of endocrine function and the development of diabetes are not uncommon, and the incidence increases as the disease progresses. Complications frequently bring the patient to the attention of the surgeon. Infection is not infrequent, possibly related to the diabetes mellitus.

Investigations

Only in the early stages of the disease will there be a rise in serum amylase. Tests of pancreatic function merely confirm the presence of pancreatic insufficiency or that more than 70 per cent of the gland has been destroyed.

Figure 68.29 Computed tomography scan in a patient with chronic pancreatitis. There is a stone obstructing the main pancreatic duct in the body of the gland with marked dilatation of the duct distal to the stone.

Pancreatic calcifications may be seen on abdominal x-ray (see Figure 68.18). CT or MRI scan will show the outline of the gland, the main area of damage and the possibilities for surgical correction (Figure 68.29; see also Figure 68.7). Calcification is seen very well on CT, but not on MRI. An MRCP will identify the presence of biliary obstruction and the state of the pancreatic duct (Figure 68.30). The use of intravenous secretin during the study may demonstrate a pancreatic duct stricture that is not apparent on a standard MRCP, but a normal-looking pancreas on CT or MRI does not rule out chronic pancreatitis. ERCP is the most accurate way of elucidating the anatomy of the duct and, in conjunction with the whole organ morphology, can help to determine the type of operation required, if operative intervention is indicated (Figures 68.15 and 68.17). Histologically proven chronic pancreatitis can, however, occur in the setting of normal findings on pancreatography. EUS can also be very useful. Sonographic findings characteristic of chronic pancreatitis include the presence of stones, visible side branches, cysts, lobularity, an irregular main pancreatic duct, hyperechoic foci and strands, dilation of the main pancreatic duct and hyperechoic margins of the main pancreatic duct. The presence of four or more of these features is highly suggestive of chronic pancreatitis.

Treatment

Most patients can be managed with medical measures. There is no single therapeutic agent that has been shown to relieve symptoms (Summary box 68.9).

Endoscopic, radiological or surgical interventions are indicated mainly to relieve obstruction of the pancreatic duct, bile duct or the duodenum, or in dealing with complications (e.g. pseudocyst, abscess, fistula, ascites or variceal haemorrhage). Decompressing an obstructed pancreatic duct can provide pain relief in some patients (the assumption is that ductal hypertension causes the pain).

Endoscopic pancreatic sphincterotomy might be beneficial in patients with papillary stenosis and a high sphincter pressure and pancreatic ductal pressure. Patients with a dominant pancreatic duct stricture and upstream dilatation may benefit by placement of a stent across the stricture. The stent should be left in for no more than 4–6 weeks as it will block. The complication rate is high, and less than two-thirds of patients experience pain relief,

Figure 68.30 Magnetic resonance cholangiopancreatography in a patient with chronic pancreatitis. Stricture of the pancreatic duct in the body of the gland (arrow), with dilatation upstream.

Summary box 68.9

Medical treatment of chronic pancreatitis

- Treat the addiction
 - Help the patient to stop alcohol consumption and tobacco smoking
 - Involve a dependency counsellor or a psychologist
- Alleviate abdominal pain
 - Eliminate obstructive factors (duodenum, bile duct, pancreatic duct)
 - Escalate analgesia in a stepwise fashion
 - Refer to a pain management specialist
 - For intractable pain, consider CT/EUS-guided coeliac axis block
- Nutritional and pharmacological measures
 - Diet: low in fat and high in protein and carbohydrates
 - Pancreatic enzyme supplementation with meals
 - Correct malabsorption of the fat-soluble vitamins and vitamin B12
 - Micronutrient therapy with methionine, vitamins C and E, selenium (may reduce pain and slow disease progression)
 - Steroids (only in autoimmune pancreatitis, for relief of symptoms)
 - Medium-chain triglycerides in patients with severe fat malabsorption (they are directly absorbed by the small intestine without the need for digestion)
 - Reducing gastric secretions may help
- Treat diabetes mellitus

Figure 68.31 Pancreatojejunostomy. The pancreatic duct is opened longitudinally, and a loop of jejunum is sutured to the duct. In the Frey procedure, the superficial part of the head of the pancreas is removed to achieve drainage.

but those who do get relief may benefit from a surgical bypass. Pancreatic duct stones may be extracted at ERCP, and this may sometimes be combined with extracorporeal shock wave lithotripsy. Pseudocysts may be drained internally under EUS guidance. Percutaneous or transgastric drainage of pseudocysts under ultrasound or CT guidance may be performed.

The role of surgery is to overcome obstruction and remove mass lesions. Some patients have a mass in the head of the pancreas, for which either a pancreatoduodenectomy or a Beger procedure (duodenum-preserving resection of the pancreatic head) is appropriate. If the duct is markedly dilated, then a longitudinal pancreatojejunostomy or Frey procedure can be of value (Figure 68.31). The natural evolution of the disease may not be altered significantly, but around half the patients get long-term pain relief. The rare patient with disease limited to the tail will be cured by a distal pancreatectomy. Patients with intractable pain and diffuse disease may plead for a total pancreatectomy in the expectation that removing the offending organ will relieve their pain. However, one should keep in mind that pancreatic function and quality of life are significantly impaired after this procedure, and the operative mortality rate is not trivial. Moreover, there is no guarantee of pain relief (approximately a third of patients get resolution, a third show some benefit, and a third see no benefit at all). Total pancreatectomy and islet autotransplantation has been reported in selected patients, but it is difficult to demonstrate any overall benefit.

Prognosis

Chronic pancreatitis is a difficult condition to manage. Patients often suffer a gradual decline in their professional, social and personal lives. The pain may abate after a surgical or percutaneous intervention, but tends to return over a period of time. In a proportion of patients, the inflammation may gradually burn out over a period of years, with disappearance of the pain, leaving only the exocrine and endocrine insufficiencies. Development of pancreatic cancer is a risk in those who have had the disease for more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and malignancy excluded.

Sphincter of Oddi dysfunction

Separate mention is warranted of this condition, which should be considered in the differential diagnosis of chronic biliary or pancreatic pain. The sphincter of Oddi is 6–10 mm long and lies within the duodenal wall. A part of it encircles the common channel, and then there are separate biliary and pancreatic components (see Figure 68.5). Scarring or stenosis of the sphincter can result from passage of stones, pancreatitis or prior endoscopic sphincterotomies. Sphincter of Oddi dyskinesia or dysfunction (SOD) is a clinical syndrome in which pain, biochemical abnormalities and dilatation of the bile duct and/or pancreatic duct are attributed to abnormal function of the sphincter of Oddi. The true incidence of SOD is unknown. Females are more commonly affected than males.

There are two types of SOD. Biliary-type SOD is characterised by biliary pain, which may be accompanied by abnormally raised liver enzymes and/or dilation of the bile duct and/or evidence of delayed emptying on biliary scintigraphy. It may be a cause of persistent post-cholecystectomy symptoms. A predominance of pancreatic problems, especially recurrent episodes

of acute pancreatitis, is known as pancreatic-type SOD. The biliary and pancreatic sphincters can be evaluated at the time of ERCP with manometry, and high sphincter pressures may be demonstrated. Sphincterotomy and/or stenting of the involved duct system may be performed if deemed appropriate. SOD is, however, associated with a particularly high risk of post-ERCP pancreatitis, and such treatments are best carried out in tertiary units by expert gastroenterologists.

In a small subgroup of patients who have experienced significant but short-lived relief with sphincterotomy or stenting, surgical transduodenal sphincteroplasty may be considered. Although SOD can cause severe symptoms (and the patient may therefore be keen to have something done), it is not fatal. However, post-ERCP pancreatitis and surgery both carry a small but definite risk of mortality.

CARCINOMA OF THE PANCREAS

Pancreatic cancer is the sixth leading cause of cancer death in the UK, and the incidence is ten cases per 100 000 population per year. Worldwide, it constitutes 2–3 per cent of all cancers and, in the United States, is the fourth highest cause of cancer death. The incidence has declined slightly over the last 25 years. There is no simple screening test; however, patients with an increased inherited risk of pancreatic cancer (Table 68.7) should be referred to specialist units for screening and counselling.

Table 68.7 Risk factors for the development of pancreatic cancer.

Demographic factors	Age (peak incidence 65–75 years) Male gender Black ethnicity
Environment/lifestyle	Cigarette smoking
Genetic factors and medical conditions	Family history Two first-degree relatives with pancreas cancer: relative risk increases 18- to 57-fold Germline <i>BRCA2</i> mutations in some rare high-risk families Hereditary pancreatitis (50- to 70-fold increased risk) Chronic pancreatitis (5- to 15-fold increased risk) Lynch syndrome Ataxia telangiectasia Peutz–Jeghers syndrome Familial breast–ovarian cancer syndrome Familial atypical multiple mole melanoma Familial adenomatous polyposis – risk of ampullary/duodenal carcinoma Diabetes mellitus

Pathology

More than 85 per cent of pancreatic cancers are ductal adenocarcinomas. The remaining tumours constitute a variety of pathologies with individual characteristics. Endocrine tumours of the pancreas are rare. They are covered in Chapter 52.

Ductal adenocarcinomas arise most commonly in the head of the gland. They are solid, scirrhous tumours, characterised by neoplastic tubular glands within a markedly desmoplastic fibrous stroma. Fibrosis is also a characteristic of chronic pancreatitis, and histological differentiation between tumour and pancreatitis can cause diagnostic difficulties. Ductal adenocarcinomas infiltrate locally, typically along nerve sheaths, along lymphatics and into blood vessels. Liver and peritoneal metastases are common. Proliferative lesions in the pancreatic ducts can precede invasive ductal adenocarcinoma. These are termed ‘pancreatic intra-epithelial neoplasia’ or PanIN, and can demonstrate a range of structural complexity and cellular atypia.

Cystic tumours of the pancreas may be serous or mucinous. Serous cystadenomas are typically found in older women, and are large aggregations of multiple small cysts, almost like bubble-wrap. They are benign. Mucinous tumours, on the other hand, have the potential for malignant transformation. They include mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). MCNs are seen in perimenopausal women, show up as multilocular thick-walled cysts in the pancreatic body or tail and, histologically, contain an ovarian-type stroma. IPMNs are more common in the pancreatic head and in older men, but an IPMN arising from a branch duct can be difficult to distinguish from an MCN. IPMNs arising within the main duct are often multifocal and have a greater tendency to prove malignant. Thick mucus seen extruding from the ampulla at ERCP is diagnostic of a main duct IPMN. Mucinous tumours can be confused with pseudocysts (see Summary box 68.8). Occasionally, lymphoepithelial cysts, lymphangiomas, dermoid cysts and intestinal duplication cysts can show up in the pancreas. Solid pseudopapillary tumour is a rare, slowly progressive but malignant tumour, seen in women of childbearing age, and manifests as a large, part-solid, part-cystic tumour.

Tumours arising from the ampulla or from the distal common bile duct can present as a mass in the head of the pancreas, and constitute around a third of all tumours in that area. Adenomas of the ampulla of Vater are diagnosed at endoscopy as polypoid submucosal masses covered by a smooth epithelium. They can harbour foci of invasive carcinoma; the larger the adenoma, the greater the risk. Biopsies taken at endoscopy may not always include the malignant focus. Endoscopic surveillance, endoscopic resection or even surgical transduodenal ampullary excision should be considered (Figure 68.32). Patients with familial adenomatous polyposis (FAP) can present with multiple duodenal polyps. Malignant transformation in a duodenal polyp is a significant cause of mortality in these patients, mandating endoscopic follow up and pancreatoduodenectomy in selected patients with high-grade dysplasia within the polyp.

Ampullary adenocarcinomas often present early with biliary obstruction. Their natural history is distinctly more favourable compared with pancreatic ductal adenocarcinoma. Ampullary carcinomas are relatively small when diagnosed, which may account for their better prognosis. Occasionally, other malignant neoplasms can arise at the ampulla, such as carcinoid tumours and high-grade neuroendocrine carcinomas.

Clinical features

Jaundice secondary to obstruction of the distal bile duct is the most common symptom that draws attention to ampullary and pancreatic head tumours. It is characteristically painless jaundice but may be associated with nausea and epigastric

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St John’s Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, The New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.
Henry Lynch, contemporary, Professor of Medicine, Creighton University, Omaha, Nebraska, USA, described the family cancer syndrome that now bears his name. Formally known as HNPCC (hereditary non-polyposis colon cancer) due to the frequency of colorectal cancers in the absence of polyposis.

Figure 68.32 A large ampullary adenoma that turned into an adenocarcinoma; the arrow indicates the ampulla. Photograph taken after resection in the form of a pancreaticoduodenectomy (courtesy of Dr Joanne Chin-Aleong).

discomfort. Pruritus, dark urine and pale stools with steatorrhoea are common accompaniments of jaundice. In the absence of jaundice, symptoms are often non-specific, namely vague discomfort, anorexia and weight loss, and are frequently dismissed by both patient and doctor. Upper abdominal symptoms in a recently diagnosed diabetic, especially in one above 50 years of age, with no family history or obesity, should raise suspicion. Occasionally, a patient will present with an unexplained attack of pancreatitis; all such patients should have follow-up imaging of the pancreas. Tumours of the body and tail of the gland often grow silently, and present at an advanced unresectable stage. Back pain is a worrying symptom, raising the possibility of retroperitoneal infiltration.

On examination, there may be evidence of jaundice, weight loss, a palpable liver and a palpable gall bladder. Courvoisier first drew attention to the association of an enlarged gall bladder and a pancreatic tumour in 1890, when he noted that, when the common duct is obstructed by a stone, distension of the gall bladder (which is likely to be chronically inflamed) is rare; when the duct is obstructed in some other way, such as a neoplasm, distension of the normal gall bladder is common. Other signs of intra-abdominal malignancy should be looked for with care, such as a palpable mass, ascites, supraclavicular nodes and tumour deposits in the pelvis; when present, they indicate a grim prognosis.

Investigation

In a jaundiced patient, the usual blood tests and ultrasound scan should be performed. Ultrasound will determine whether or not the bile duct is dilated. If it is, and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is a contrast-enhanced CT scan (see Figure 68.8). In the majority of instances, this should establish if there is a tumour in the pancreas and if it is resectable. The presence of hepatic or peritoneal metastases, lymph node metastases distant from the pancreatic head, encasement of the superior mesenteric, hepatic or coeliac artery by tumour are clear contraindications to surgical

resection. Tumour size, continuous invasion of the duodenum, stomach or colon, and lymph node metastases within the operative field are not contraindications. If the tumour abuts or minimally invades the portal or superior mesenteric vein, this is not a contraindication to surgery (as part of the vein can be resected if necessary), but complete encasement and occlusion of the vein is. MRI and MRA can provide information comparable to CT.

ERCP and biliary stenting should be carried out if there is any suggestion of cholangitis, if there is diagnostic doubt (small ampullary lesions may not be seen on CT, and ERCP is the best way to identify them), if the patient is deeply jaundiced (serum bilirubin $>250 \mu\text{mol/L}$), or there are distressing symptoms (e.g. pruritus) and there is likely to be a delay between diagnosis and surgery. It relieves the jaundice and can also provide a brush cytology or biopsy specimen to confirm the diagnosis (see Figures 68.13, 68.14 and 68.19). Otherwise, however, preoperative ERCP and biliary stenting is not mandatory in patients with resectable disease; there is evidence to suggest that it is associated with a slightly higher incidence of infective complications after surgery. The prothrombin time should be checked, and clotting abnormalities should be corrected with vitamin K or fresh-frozen plasma prior to ERCP. If a stent is placed in a patient who may undergo resection, it should be a plastic stent or a **covered** metal stent that can be easily removed.

EUS is useful if CT fails to demonstrate a tumour, if tissue diagnosis is required prior to surgery (e.g. a mass has developed on a background of chronic pancreatitis and a distinction needs to be made between inflammation and neoplasia), if vascular invasion needs to be confirmed and in separating cystic tumours from pseudocysts (Figure 68.33; see also Figure 68.20). Transduodenal or transgastric FNA or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity. Percutaneous transperitoneal biopsy of potentially resectable pancreatic tumours should be avoided as far as possible. Histological confirmation of malignancy is desirable but not essential, particularly if the imaging clearly demonstrates a resectable tumour. The lack of a tissue diagnosis should not delay appropriate surgical therapy. In patients judged to have unresectable disease, tissue diagnosis should be obtained prior to starting palliative therapy.

Diagnostic laparoscopy prior to an attempt at resection can spare a proportion of patients an unnecessary laparotomy by identifying small peritoneal and liver metastases. It can be combined with laparoscopic ultrasonography. The tumour marker CA19-9 is not highly specific or sensitive, but a baseline level should be established; if it is initially raised, it can be useful later in identifying recurrence.

Management

At the time of presentation, more than 85 per cent of patients with ductal adenocarcinoma are unsuitable for resection because the disease is too advanced. If imaging shows that the tumour is potentially resectable, the patient should be considered for surgical resection, as that offers the only (albeit small) chance of a cure. Comorbidities should be carefully taken into account. Biological rather than chronological age should be the consideration. If a cystic tumour is encountered, no matter how large, surgical resection should be considered, as it carries a reasonable chance of cure. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare

Figure 68.33 (a) Carcinoma of the ampulla as seen at endoscopy. (b) Appearance of the same tumour (arrow) on endoscopic ultrasound (courtesy of Dr Peter Fairclough).

tumours and the neuroendocrine lesions should also be resected if at all possible. For those patients who have inoperable disease, palliative treatment should be offered.

Surgical resection

The standard resection for a tumour of the pancreatic head or the ampulla is a pylorus-preserving pancreatoduodenectomy (PPPD). This involves removal of the duodenum and the pancreatic head, including the distal part of the bile duct. The original pancreatoduodenectomy as proposed by Whipple included resection of the gastric antrum. Preserving the antrum and the pylorus is thought to result in a more physiological outcome with no difference in survival or recurrence rates. The Whipple procedure is now reserved for situations in which the entire duodenum has to be removed (e.g. in FAP) or where the tumour encroaches on the first part of the duodenum or the distal stomach and a PPPD would not achieve a clear resection margin. Total pancreatectomy is warranted only in situations

where one is dealing with a multifocal tumour (e.g. a main duct IPMN), or the body and tail of the gland are too inflamed or too friable to achieve a safe anastomosis with the bowel. The PPPD procedure includes a local lymphadenectomy. Extended lymphadenectomy has not been shown to be beneficial in improving survival and is associated with increased morbidity. If the tumour is adherent to the portal or superior mesenteric vein, but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure, and the outcomes are similar.

For tumours of the body and tail, distal pancreatectomy with splenectomy is the standard. Infiltration of the splenic artery or vein by the tumour is not a contraindication to resection. When resecting the pancreatic tail for a benign lesion, one may attempt to preserve the spleen if possible. When removing the spleen, prior vaccinations against pneumococci, meningococci and *Haemophilus influenzae* B should be administered, and subsequent antibiotic prophylaxis given (see Chapter 66).

Attempts to downstage unresectable disease with chemotherapy or chemoradiation and render it resectable are rarely successful. Neoadjuvant chemotherapy or chemoradiation for resectable disease should only be considered within a clinical trial; it carries the risk that the disease may progress despite the neoadjuvant therapy and become unresectable.

Pancreatoduodenectomy

The patient's coagulation screen should be checked preoperatively and adequate hydration ensured. The patient should be aware of the diagnosis, the gravity of the operation and the risks involved. The operation has three distinct phases:

- exploration and assessment;
- resection;
- reconstruction.

A cholecystectomy is performed. The bile duct and hepatic artery are exposed, removing the lymphatic tissue in this area. Exposure of the hepatic artery enables division of the gastroduodenal artery and visualisation of the portal vein. The distal part of the gastric antrum is mobilised. The duodenum and right colon are mobilised from the retroperitoneal tissues. The superior mesenteric vein is exposed inferior to the pancreatic neck. Careful dissection into the plane between the vein and the pancreatic substance (see Figure 68.2) will reveal whether the tumour is adherent to the vein. At this juncture, a decision has to be made whether to proceed to the next phase of resection or not. If resection is to be performed, the fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the upper jejunum can be brought into the supracolic compartment. The jejunum is divided 20–30 cm downstream from the duodenojejunal flexure, and the mesentery of the proximal jejunum is detached. The first part of the duodenum is divided. The neck of the pancreas is divided, and then the uncinate process is separated from the superior mesenteric artery and vein working up towards the upper bile duct, which is divided, releasing the specimen (Figure 68.34). Retroperitoneal lymph nodes within

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, Columbia University, New York, NY, USA, began to perform two-stage pancreatoduodenectomies in 1934 and shortened the procedure into a one-stage process in 1940.

Alessandro Codivilla (1861–1912) and **Walter Kausch** (1867–1928) had performed the operation before him, but Whipple was the surgeon who established pancreatoduodenectomy as an operation.

Wenzel Treitz, 1819–1872, Professor of Anatomy and Pathology, at Krakow, Poland, and later at Prague, Czech Republic. He was involved in the struggle for Czech nationalism.

Figure 68.34 Resection of the head of the pancreas in a pylorus-preserving pancreaticoduodenectomy.

Figure 68.35 Reconstruction after a pylorus-preserving pancreaticoduodenectomy.

the operative field are completely removed with the specimen. Reconstruction is carried out as in Figure 68.35. The pancreatic stump, the divided bile duct and the duodenal stump are anastomosed on to jejunum, in that order. Some surgeons prefer to anastomose the pancreas to the posterior wall of the stomach instead; others prefer to create a separate Roux loop of the jejunum and anastomose the pancreas to that. The operation should take between 3 and 6 hours. Blood loss should be low, and transfusion is often not necessary. The patients are usually nursed in a high dependency area for the first 24–48 hours after surgery. Prolonged nasogastric drainage is unnecessary, and early feeding can be commenced.

Resection for pancreatic cancer should be carried out in specialist units. There is a clear correlation between higher caseload volume and lower hospital mortality and morbidity. PPPD should carry a mortality of no more than 3–5 per cent. The morbidity remains high, with some 30–40 per cent of patients developing a complication in the postoperative period. These complications are usually infective, but a leak from the anastomosis between the pancreas and the bowel is known to occur in at least 10 per cent of patients, and this may give rise to major complications. Octreotide may be administered in the

perioperative period to suppress secretion and reduce the likelihood of a leak, but the evidence for its efficacy is still debatable. Following surgical resection, the pathological tumour–node–metastasis (TNM) stage should be documented.

Adjuvant therapy

The reported five-year survival following resection of a pancreatic adenocarcinoma ranges from 7 to 25 per cent. The median survival is 11–20 months. Considering that, at best, 15 per cent of patients have resectable disease to begin with, this means only two or three of 100 patients with this disease can expect to survive to five years. Moreover, recurrences can and do show up even beyond the five-year cut off. It should be emphasised, however, that these depressing statistics apply to ductal adenocarcinomas. Patients with resected ampullary tumours have a five-year survival of 40 per cent, and cystic tumours and neuroendocrine tumours can often be cured by surgical resection.

The high recurrence rate following resection has inevitably led to the consideration of adjuvant treatments to improve outcome. In a large multicentre European study (ESPAC-1), adjuvant radiotherapy or chemoradiotherapy was shown to confer no advantage, but chemotherapy with 5-fluorouracil (5-FU) provided an overall benefit; median survival with chemotherapy was 20 months compared with 16 months without. Another trial (ESPAC-3) showed that gemcitabine works equally well. Most patients with resected ductal adenocarcinoma are now offered adjuvant chemotherapy, using gemcitabine or 5-FU. A further trial is in progress of gemcitabine alone versus gemcitabine with capecitabine (a fluorouracil that can be taken orally). Some centres continue to offer chemoradiotherapy, particularly in patients with involved (R1) resection margins, and further trials of adjuvant chemoradiation are also in progress.

Palliation

The median survival of patients with unresectable, locally advanced, non-metastatic pancreatic cancer is between six and ten months and, in patients with metastatic disease, it is two to six months.

If unresectable disease is found in the course of a laparotomy that was commenced with the intent to resect, a choledochenterostomy and a gastroenterostomy should be carried out to relieve (or pre-empt) jaundice and duodenal obstruction. The bile duct may be anastomosed to the duodenum, or to a loop of jejunum. It is preferable to use the bile duct rather than the gall bladder. Cholecystojejunostomy is easier to perform, but the bile must then drain through the cystic duct, which is narrow and, if the cystic duct is inserted low into the bile duct, it is vulnerable to occlusion by tumour growth. A coeliac plexus block can also be administered. A transduodenal Trucut biopsy of the tumour should be obtained.

In patients found to have unresectable disease on imaging, jaundice is relieved by stenting at ERCP (Figure 68.36b). Stents may be made of plastic or self-expanding metal mesh. Plastic stents are cheaper but tend to occlude faster and, if the patient is likely to have a longer life expectancy, a metal stent can be used. If the patient is not a suitable candidate for endoscopic biliary stenting, a percutaneous transhepatic stent can be placed (Figure 68.36a). Obstruction of the duodenum occurs in approximately 15 per cent of cases. If this occurs early in the course of the disease, surgical bypass by gastrojejunostomy is appropriate but, if it is late in the course of the disease, then the use of expanding

Figure 68.36 Approaches to biliary and duodenal stenting. (a) Percutaneous transhepatic cholangiography (PTC) followed by cannulation of the biliary system and percutaneous placement of a biliary stent (mesh metal in this instance); (b) endoscopic retrograde cholangiography (ERCP) and placement of a biliary stent; (c) endoscopic placement of a duodenal stent (mesh metal).

metal stents inserted endoscopically is preferable, as many of these patients have prolonged delayed gastric emptying following surgery (Figure 68.36c). If both biliary and duodenal metal stents are to be placed endoscopically, the biliary one should be placed first.

If no operative procedure is undertaken, an EUS-guided or percutaneous biopsy of the tumour should be performed before consideration of chemotherapy or chemoradiation. The role of chemotherapy in the management of pancreatic cancer remains ill defined. If the tumour is a lymphoma, then benefit is without

doubt. Lymphomas of the pancreas are rare and constitute less than 3 per cent of all pancreatic cancers. For patients with ductal adenocarcinoma, 5-FU or gemcitabine will produce a remission in 15–25 per cent, while the remainder will receive no benefit from the therapy. No long-term cures have been described with chemotherapy or radiotherapy.

Steatorrhoea is treated with enzyme supplementation. Diabetes mellitus, if it develops, is treated with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block (Summary box 68.10).

Summary box 68.10

Palliation of pancreatic cancer

- Relieve jaundice and treat biliary sepsis
 - Surgical biliary bypass
 - Stent placed at ERCP or percutaneous transhepatic cholangiography
- Improve gastric emptying
 - Surgical gastroenterostomy
 - Duodenal stent
- Pain relief
 - Stepwise escalation of analgesia
 - Coeliac plexus block
 - Transthoracic splanchnicectomy
- Symptom relief and quality of life
 - Encourage normal activities
 - Enzyme replacement for steatorrhea
 - Treat diabetes
- Consider chemotherapy

LEARNING OBJECTIVES

To appreciate:

- The basic anatomy and physiology of the small and large intestines
- The range of conditions that may affect the intestines

To understand:

- The aetiology and pathology of common intestinal conditions
- The principles of investigation of intestinal symptoms

- The importance of non-surgical management of intestinal problems
- The principles of intestinal surgery
- That complex intestinal problems are best managed by a multidisciplinary team
- The management of acute surgical problems of the intestines

ANATOMY OF THE SMALL AND LARGE INTESTINES

Small intestine

Although the duodenum is anatomically indistinguishable from the small intestine, it is subject to some specific pathologies and surgical therapies, so, in purely surgical terms may be regarded as a distinct entity, covered in Chapter 63. The length of the small bowel may vary from 300 to 850 cm between the duodeno-jejunal (DJ) flexure to the ileocaecal valve. It is notoriously difficult to establish the length of the small intestine, and estimates gathered at surgery, post-mortem and during radiological investigations vary widely, even in the same individual. In addition, there may be considerable interindividual variability and the small intestine is believed to be longer in men.

The proximal 40 per cent of the small intestine is referred to as the jejunum; the remainder is the ileum. There is no clear demarcation between jejunum and ileum, but the small bowel does change gradually in character from proximal to distal. The jejunum tends to have a wider diameter and a thicker wall, with more prominent mucosal folds (**valvulae conniventes**), while the ileum has a thicker, more fatty mesentery with more complex arterial arcades. The ileum also contains larger aggregates of lymph nodes (Peyer's patches), which can occasionally become lead points in intussusception in childhood.

The small intestine has a very rich blood supply, from the superior mesenteric artery, while venous drainage is via the portal venous system, into which the superior mesenteric vein drains blood rich in nutrients after a meal. This arrangement facilitates processing of the nutrients by the liver, into which

the portal vein drains in turn. The lymphatic drainage of the small intestine follows the arterial supply. The small intestine has a rich autonomic innervation arising from the splanchnic nerves, which contribute a dense network of sympathetic fibres around the superior mesenteric artery and its branches. Referred pain from the small intestine is usually felt in the periumbilical region (T10). The blood and nerve supply to the small intestine all runs in the attached mesentery which originates on the posterior abdominal wall and runs obliquely downwards to the right between the DJ flexure to the left of the second lumbar vertebra and the right sacroiliac joint. Surgical resection of the small bowel requires careful division not only of the arteries and veins, but also the mesentery (see Summary box 69.1).

Summary box 69.1

Anatomy of the small and large intestine

- Small intestine
 - Comprises jejunum and ileum
 - Has valvulae conniventes
 - Blood supply from superior mesenteric artery
- Large intestine
 - Comprises caecum, ascending, transverse, descending and sigmoid colon
 - Has appendices epiploicae and taenia coli
 - Blood supply from branches of superior and inferior mesenteric arteries
 - Marginal artery runs round the length of the colon

Valvulae conniventes describes a fold of mucus membrane that passes across two-thirds of the bowel circumference.

Johann Conrad Peyer, 1653–1712, Professor of Logis, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

Eric Adolph von Willebrand, 1879–1949, physician, Diakonissanstalts Hospital, Helsinki (Helsingfors), Finland, described hereditary pseudo-haemophilia in 1926.

Norman Stanley Williams, contemporary, President, Royal College of Surgeons of England and Professor of Surgery, Barts and The London School of Medicine and Dentistry, London, UK.

Large intestine

The large intestine begins at the ileocaecal valve and extends to the anus. It is divided into the caecum, with its attached vermiform appendix (discussed in Chapter 71), the ascending colon, which runs up to the hepatic flexure, the transverse colon with attached greater omentum, running up to the splenic flexure, the descending colon, sigmoid and rectum (discussed separately in Chapter 72). The large intestine is approximately 1.5 m long, although at colonoscopy the bowel can be straightened so the caecum can be reached with as little as 70 cm of colonoscope.

The large intestine is less mobile than the small bowel as the ascending and descending colon are fixed to the retroperitoneum following embryological rotation. The colon is also distinguished by having fat-filled peritoneal tags known as **appendices epiploicae** and the presence of **taeniae**. The **taenia coli** are three flat bands of longitudinal muscle that run the length of the large intestine from the appendix base to the rectosigmoid junction and they act to pull the colon into its typical sacculated state, producing a series of **haustrations**. Distended small and large intestine can be distinguished on an abdominal radiograph as the small bowel has complete transverse markings caused by the valvulae conniventes, while the colon has incomplete lines from the sacculations caused by the taeniae. The important posterior relations of the caecum and ascending colon are the right ureter, right gonadal vessels and duodenum, and these must be carefully protected at surgery. Similarly, the left ureter, left gonadal vessels and tail of the pancreas must be protected when operating on the left colon.

The blood supply of the large intestine is derived from branches of the superior mesenteric artery proximally as far as the distal transverse colon (which is derived embryologically from the primitive midgut) and the inferior mesenteric artery and its branches more distally (derived from the primitive hindgut). Adjacent branches of the superior and inferior mesenteric arteries anastomose so there is usually a complete vascular supply along the colon named the 'marginal artery of Drummond'. This vessel is often the key blood supply to the vascular arcades ensuring adequate perfusion of a colonic anastomosis, but blood flow in the 'watershed' area of the splenic flexure representing the junction between the superior and inferior mesenteric supply may be quite tenuous. The consequences of this might be, for example, that sudden occlusion of the inferior mesenteric artery may leave the area of the splenic flexure (at the most distal point of supply from the superior mesenteric artery) poorly perfused, leading to an ischaemic colitis. Venous and lymphatic drainage of the colon follows the arterial supply and as for the small intestine system, venous drainage is into the portal system. High ligation of the artery supplying a segment of colon will therefore remove the lymph nodes draining the area, a key technical point in cancer surgery. The nerve supply to the large intestine is derived from the splanchnic nerves, via a dense sympathetic plexus surrounding the superior and inferior mesenteric arteries. Visceral pain from the part of the colon supplied by the superior mesenteric

artery is thus felt, like that of the small intestine, in the periumbilical region, while pain from the colon distal to that point is felt suprapubically (T12–L1).

PHYSIOLOGY OF THE SMALL AND LARGE INTESTINES

Small intestine

The main function of the small intestine is the digestion of food and the absorption of nutrients and fluid. Carbohydrates and proteins are broken down by pancreatic enzymes, but the final hydrolysis takes place at the brush border of the jejunum after which they are absorbed. The products of fat digestion, fatty acids and monoglycerides separate from bile salts in the jejunum and are absorbed for further processing. The jejunum is the principal site for digestion and absorption of fluid, electrolytes, iron, folate, fat, protein and carbohydrate, but the absorption of bile salts and vitamin B12 occurs in the terminal ileum where there are specific transporters. If the jejunum is resected, the ileum can assume all the required absorptive functions, but resection of the terminal ileum will result in a diminished bile salt pool, B12 deficiency and may lead to deficiency of the fat-soluble vitamins A, D and K.

The small intestine plays an important role in the metabolism of plasma lipoproteins, as it is the main site of synthesis of high-density, low-density and very low-density lipoproteins (HDL, LDL, VLDL). The small bowel also synthesises intestinal hormones, which interact with the enteric nervous system to modulate intestinal function, growth and differentiation.

Large intestine

The principal function of the colon is absorption of water; 1000 mL of ileal contents enter the caecum every 24 hours of which only about 150–250 mL is excreted as faeces. Sodium absorption is efficiently accomplished by an active transport system, while chloride and water are absorbed passively following gradients established by the sodium pump. Fermentation of dietary fibre in the colon by the normal colonic microflora (principally anaerobic bacteria, such as bacteroides and bifidobacteria) leads to the generation of short chain fatty acids (SCFAs) such as butyrate, which is an important metabolic fuel for the colonic mucosa and may also contribute to normal daily energy requirements. Thus, diversion of the faecal stream (for example by a temporary 'loop' ileostomy) may lead to inflammatory changes in the colon downstream, a condition referred to as 'diversion colitis'. Some absorption of nutrients including glucose, fatty acids, amino acids and vitamins can also take place in the colon, although under normal circumstances only a tiny amount of this occurs.

Colonic motility is variable. In general, faecal residue reaches the caecum 4 hours after a meal and the rectum after 24 hours. Passage of stool is not orderly, however, because of mixing within the colon. It is thus common for residue from a single meal to still be passed 4 days later.

INFLAMMATORY BOWEL DISEASE

By definition, the term 'inflammatory bowel disease' is reserved for conditions characterised by the presence of **idiopathic** intes-

Charles Horace Mayo, 1865–1939, surgeon, The Mayo Clinic, Rochester, MN, USA. He and his brother, **William James Mayo** (1861–1939), joined their father's private practice in Rochester. This practice became The Mayo Clinic. Their father, **William Worrall Mayo**, was born in Manchester, UK, in 1919.

Sir David Drummond, 1852–1932, English physician.

Gabriele Fallopio (Fallopius), 1523–1562, Professor of Anatomy, Surgery and Botany, Padua, Italy.

tinal inflammation, i.e. ulcerative colitis (UC) and Crohn's disease (CD). Conditions such as infective or ischaemic colitis or enteritis are thus excluded. Although the availability of population genetics and molecular biology has contributed to our understanding of the pathogenesis of inflammatory bowel disease, the cause of these conditions remains unknown.

ULCERATIVE COLITIS

Ulcerative colitis is a disease of the rectum and colon with extraintestinal manifestations. The incidence is 10 per 100 000 in the UK with a prevalence of 160 per 100 000. The prevalence of UC is stable (unlike Crohn's disease, which is increasing). UC is said to be more common in the Ashkenazi Jewish population and affects men and women equally in early life, although it is said to be more common in males in later life. It is most commonly diagnosed between the ages of 20 and 40. There is a marked geographical distribution of the disease which is far more common in the United States and Western Europe, but relatively rare in the Far East and the Tropics. The incidence in the Asian population of the UK seems to be determined by where childhood was spent. Asians who spent their childhood before the age of 14 in Asia have a much lower incidence of UC than Asians born and raised in the UK, suggesting an important effect of environmental exposure in childhood.

Aetiology

The cause of UC is unknown. There is clearly a genetic contribution as 10–20 per cent of patients with UC have a first-degree relative with inflammatory bowel disease. UC is more common in Caucasians than in the Afro-Caribbean or Asian population. No causative link with any specific organisms has been identified, although studies of patients with severe colitis have suggested a reduction in the number of anaerobic bacteria and a reduction in the variability of bacterial strains in the colon. Whether this is a primary feature of the disease or a secondary consequence of mucosal inflammation is unclear. Animal studies, using models of colitis, have suggested that the presence of a bacterial flora is important in the development of colitis, even if no specific organism is involved. For example, mice with a genetic deficiency predisposing them to colitis (e.g. strains with the genes for IL-10 or PGP knocked out) appear to be protected if reared in a germ-free environment. Although it has been suggested that the mechanism of UC may relate to a primary abnormality of mucosal permeability, resulting in bacterial antigens being able to cross the colonic mucosal barrier and thus triggering an inflammatory response, the data to support this hypothesis are unclear and more recent studies in animal models have shown that genes involved in mucosal inflammation and bacterial recognition are already activated long before evidence of abnormal permeability or overt inflammation appear. This suggests that the demonstration of increased colonic mucosal permeability in colitis may be a consequence, rather than a cause of the disease. Unlike Crohn's disease, smoking seems to have a protective effect in UC and has even been the basis of therapeutic trials of nicotine therapy. Patients often comment that relapses are associated with periods of stress, but personality and psychiatric profiles in patients with UC are the same as those of the normal population.

Pathology

In virtually all cases, the disease starts in the rectum and extends proximally in continuity. The rectum is involved in all circumstances except in those using topical rectal preparations (rectal sparing). Failure of colonic inflammation to adhere to this pattern should lead to strong suspicion that the diagnosis is not one of UC. Colonic inflammation in UC is diffuse, confluent and superficial, primarily affecting the mucosa and superficial submucosa. In very severe cases, the inflammation may extend full thickness through the wall of the colon, making interpretation difficult. Chronic mucosal ulceration is associated with formation of granulation tissue and regeneration, leading to a polyp-like appearance, 'pseudopolyps', which occurs in almost one-quarter of cases. Strictureing in UC is very unusual and should prompt urgent assessment because of the possibility of coexisting carcinoma. A small proportion of patients with colonic dysplasia may develop irregular mucosal swellings (dysplasia-associated lesions or mass, DALMs), which are highly predictive of the likelihood of coexisting carcinoma.

Histological examination reveals an increase in inflammatory cells in the lamina propria, the walls of the crypts of Lieberkuhn are infiltrated by inflammatory cells and there are crypt abscesses. There is depletion of goblet cell mucin. With time, precancerous changes can develop (dysplasia). The precise incidence of dysplasia in UC is unclear. It seems to increase with time and may range from 2 per cent, up to 18 per cent at 30 years. Dysplasia is classified into low- or high-grade dysplasia. In general, high-grade dysplasia is regarded as an absolute indication for colectomy, as 40 per cent of colectomy specimens in which high-grade dysplasia was detected will have evidence of a colorectal cancer. In contrast, optimum management of low-grade dysplasia is currently controversial. Although the decision to proceed to colectomy must be individualized, 10–30 per cent of patients with low-grade dysplasia will have a cancer at colectomy. The progression rate of low-grade dysplasia to invasive cancer is unclear, and it is likely that many cancers in patients with low-grade dysplasia develop without an intervening period of high-grade dysplasia.

Symptoms

Clinical presentation depends in large part on the extent of disease and the presence or otherwise of complications (see Summary box 69.2). If confined to the rectum (proctitis), there is usually no systemic upset and extra-alimentary manifestations are rare. The main symptoms will be rectal bleeding, tenesmus and mucous discharge. The disease remains confined to the rectum in 90 per cent of cases but proctitis may spread proximally over time. Colitis is almost always associated with bloody diarrhoea and urgency that can be incapacitating. Pain is unusual. Children with poorly controlled colitis may have impaired growth. The more extensive the disease, the more likely extraintestinal manifestations are to occur. Extensive colitis is also associated with systemic illness, characterised by malaise, loss of appetite and fever. Diarrhoea may be profuse and bloody, resulting in anaemia, hypoproteinaemia and electrolyte disturbance. Approximately 30 per cent of patients have inflammation extending to the sigmoid colon and spread proximal to the splenic flexure occurs in 20 per cent.

Summary box 69.2**Complications of ulcerative colitis**

- Acute
 - Toxic dilatation
 - Perforation
 - Haemorrhage
- Chronic
 - Cancer
 - Extra-alimentary manifestations: skin lesions, eye problems and liver disease

Classification of colitis severity

The assessment of severity of UC is determined by frequency of bowel action and the presence of systemic signs of illness:

- **Mild disease** is characterised by fewer than four stools daily, with or without bleeding. There are no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR).
- **Moderate disease** corresponds to more than four stools daily, but with few signs of systemic illness. There may be anaemia (but not sufficient to require transfusions). Abdominal pain may occur. Inflammatory markers, including ESR and C-reactive protein (CRP) are often raised.
- **Severe disease** corresponds to more than six bloody stools a day, and evidence of systemic illness with fever, tachycardia, anaemia and raised inflammatory markers. Hypoalbuminaemia is common and an ominous finding.
- **Fulminant disease** is associated with more than ten bowel movements daily, fever, tachycardia, continuous bleeding, anaemia, hypoalbuminaemia, abdominal tenderness and distension, blood transfusion requirement and in the most severe cases, progressive colonic dilation ('toxic megacolon'). This is a very significant finding, suggestive of disintegrative colitis and an indication for immediate surgery if colonic perforation is to be avoided.

Extraintestinal manifestations

Arthritis occurs in around 15 per cent of patients and is of the large joint polyarthropathy type, affecting knees, ankles, elbows and wrists. Sacroiliitis and ankylosing spondylitis are 20 times more common in patients with UC than the general population and are associated with HLA-B27. Sclerosing cholangitis is associated with UC and can progress to cirrhosis and hepatocellular failure. Patients with UC and sclerosing cholangitis are also at a greater risk of development of large bowel cancer. Cholangiocarcinoma is an extremely rare association and its frequency is not influenced by colectomy. The skin lesions erythema nodosum and pyoderma gangrenosum are associated with UC and both normally get better with good colitis control. The eyes can also be affected with uveitis and episcleritis.

Acute colitis

Around 5 per cent of patients present with severe acute (fulminant) colitis characterised by frequent bloody diarrhoea, weight

loss and dehydration. Intensive medical treatment and fluid resuscitation leads to remission in 70 per cent, but the rest will require urgent surgery. Toxic dilatation should be suspected in patients with active colitis who develop severe abdominal pain and confirmed by the presence on a plain abdominal radiograph of colon with a diameter of more than 6 cm (megacolon, Figure 69.1). A reduction in stool frequency is not always a sign of improvement in patients with severe UC, and the presence of a falling stool frequency, abdominal distension and abdominal pain (resulting from progression of the inflammatory process through the colonic wall) are strongly suggestive of the development of disintegrative colitis and impending perforation. Severe UC must be differentiated from dysentery, typhoid and amoebic colitis (which can also lead to colonic perforation). Plain abdominal radiographs should be obtained daily in patients with severe colitis, and a progressive increase in diameter in spite of medical therapy is an indication for surgery. Colonic perforation in UC is a grave complication with a mortality rate of 40 per cent. Steroids may mask the physical signs. Severe haemorrhage is uncommon (1–2 per cent), but may occasionally require urgent surgical intervention.

Cancer risk in colitis

The risk of cancer in ulcerative colitis increases with duration of disease. At ten years from diagnosis, it is around 1 per cent. This increases to 10–15 per cent at 20 years and may be as high as 20 per cent at 30 years. There is some evidence to suggest that these figures may be an overestimate of cancer risk and that good control of colonic inflammation may significantly reduce risk. Nevertheless, most patients with pancolitis of more than ten years' duration should be entered into screening programmes in order to detect clinically silent dysplasia, which is predictive of increased cancer risk. The value of screening programmes remains somewhat controversial, however, with most UC patients who develop cancer (approximately 3.5 per cent) presenting with their tumours in between attendances for screening colonoscopy. Carcinoma is more likely to occur if the whole colon is involved (Figure 69.2) or if the disease started early in life. Carcinomatous change, often atypical and high grade, may occur at many sites at once. Colonoscopic

Figure 69.1 Fulminating ulcerative colitis with toxic dilatation of the transverse colon (courtesy of Dr Ian Talbot, St Mark's Hospital, London).

surveillance with multiple biopsies is advised to detect dysplasia, which can occur in a flat mucosa, or a DALM. If on biopsy, there is epithelial dysplasia, surgery should be considered, as cancers may be found in 40 per cent of colectomy specimens for colitis-associated dysplasia.

Investigations

Endoscopy and biopsy

Rigid/flexible sigmoidoscopy can detect proctitis in the clinic: the mucosa is hyperaemic and bleeds on touch, and there may be a purulent exudate. Where there has been remission and relapse, there may be the presence of regenerative mucosal nodules or pseudopolyps. Later, tiny ulcers may be seen that appear to coalesce. This is quite different from the picture of amoebic dysentery, in which there are large, deep ulcers with intervening normal mucosa. Colonoscopy and biopsy has a key role in diagnosis and management:

- to establish the extent of inflammation;
- to distinguish between UC and Crohn’s colitis (although this can be exceptionally difficult, Table 69.1);
- to monitor the response to treatment;
- to assess long-standing cases for malignant change.

In the last case, detailed colonoscopic assessment using dye-spray to look for subtle mucosal abnormalities and taking multiple random biopsies every 10 cm is required.

Radiology

A plain abdominal film may indicate the severity of disease in the acute setting and is particularly valuable in demonstrating the development of toxic megacolon (Figure 69.3). Faeces are present only in parts of the colon that are normal or only mildly inflamed. Mucosal islands can sometimes be seen. Small bowel loops in the right lower quadrant may be a sign of severe disease.

Figure 69.2 Resection specimen from a patient with long-standing ulcerative colitis showing a narrow tubular colon with areas of cancerous change in the rectum and sigmoid (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

Table 69.1 Distinguishing ulcerative colitis and Crohn’s disease.

	Ulcerative colitis	Crohn’s disease
Macroscopic		
Distribution	Colon/rectum	Anywhere in the gastrointestinal tract
Rectum	Always involved	Often spared
Perianal disease	Rare	Common
Fistula formation	Rare	Common
Stricture	Rare	Common
Microscopic		
Layers involved	Mucosa/submucosa	Full thickness
Granulomas	No	Common
Fissuring	No	Common
Crypt abscesses	Common	Rare

Figure 69.3 Supine abdominal radiograph in toxic megacolon. The transverse colon is dilated (7 cm), there is no formed residue in the colon, and large mucosal islands are present in the ascending colon and hepatic flexure. No haustration is present in the transverse colon, which distinguishes this from ileus of obstruction. Mucosal islands are due to oedematous remnants or mucosa where there has been extensive ulceration (courtesy of Dr C Bartram, St Mark’s Hospital, London, UK).

Barium enema has been replaced by computed tomography (CT) in the majority of centres, although a contrast study will give an excellent view of loss of haustra, especially in the distal colon, pseudopolyps and in chronic cases a narrow, featureless, shortened 'hosepipe' colon (Figure 69.4). CT findings in pancolitis may show significant thickening of the colonic wall, as well as inflammatory stranding in the colonic mesentery (Figure 69.5).

Bacteriology

A stool specimen should be sent for microbiology analysis when UC is suspected, in order to exclude infective colitides, notably *Campylobacter*, which may be very difficult to distinguish from acute severe UC. Other infective causes include *Shigella* and *amoebiasis*. Pseudomembranous colitis occurs in hospital patients on antibiotic treatment and, occasionally, those on non-steroidal anti-inflammatory drugs (NSAIDs). The causative organism is *Clostridium difficile*. Immunocompromised patients are at risk of infective proctocolitis from cytomegalovirus and *cryptosporidia*.

Treatment

Effective treatment of UC requires a multidisciplinary approach to management. This involves the gastroenterologist, nurses, nutritionist, enterostomal therapists and occasionally clinical psychologists and social workers, as well as the surgeon (see Summary box 69.3).

Figure 69.4 Double-contrast barium enema showing left-sided ulcerative colitis with a tubular left colon compared with a normal right colon (courtesy of Dr D Nolan, John Radcliffe Hospital, Oxford, UK).

Figure 69.5 Computed tomographic scan demonstrating colitis with thickened colonic wall and inflammatory stranding in the mesentery (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

Summary box 69.3

Principles of management of ulcerative colitis

- Many patients can be adequately maintained for years on medical therapy
- Toxic dilatation must be suspected in any colitic patient who develops severe abdominal pain; missed colonic perforation is associated with a high mortality
- Colitic patients are at increased risk of developing cancer; those with pancolitis of long duration are most at risk

Medical treatment

Medical therapy is based on anti-inflammatory agents. The 5-aminosalicylic acid (5-ASA) derivatives can be given topically (per rectum) or systemically. They act as inhibitors of the cyclo-oxygenase (COX) enzyme system and are formulated to protect the aspirin-related drug from degradation before reaching the colon. They can be used long term as maintenance therapy. Corticosteroids are the mainstay of treatment for any 'flare up', either topically or systemically and have a widespread anti-inflammatory action. The immunosuppressive drugs azathioprine and cyclosporin can be used to maintain remission and as 'steroid-sparing' agents. More recently, monoclonal antibodies have entered clinical practice; infliximab and adalimumab both act against tumour necrosis factor alpha, which has a central role in inflammatory cascades.

Proctitis

The majority of patients can be managed with rectal steroids for an acute attack and oral 5-ASA compounds to maintain remission. Occasionally, a reducing course of oral steroids is required. It is very unusual for patients with purely rectal disease to require surgery.

Acute colitis

Patients with a mild attack (up to four motions a day) usually respond to a course of oral prednisolone given over a 3- to 4-week period. One of the 5-ASA compounds can be given concurrently. A moderate attack often responds to oral prednisolone, twice-daily steroid enemas and 5-ASA. Failure to achieve remission as an outpatient is an indication for admission. Severe attacks of UC occur in up to 10 per cent of patients and are emergencies requiring hospital admission. Regular assessment of vital signs, weight and the abdomen is required. A stool chart should be kept and a plain abdominal radiograph is taken daily and inspected for dilatation of the transverse colon. The presence of mucosal islands or intramural gas on plain radiographs (see Figure 69.6), increasing colonic diameter or a sudden increase in pulse and temperature may indicate a colonic perforation. Fluid and electrolyte balance is maintained, anaemia corrected and adequate nutrition is provided, sometimes intravenously in severe cases. If the patient is not having immediate surgery, then oral nutrition is important. It is important to ensure that calorie and nitrogen requirements are met by dietary supplementation or intravenous feeding. The patient is treated with intravenous hydrocortisone four times daily, as well as rectal steroids. There is no evidence that antibiotics modify the course of a severe attack. If there is failure to gain an improvement within 48 hours of commencing high-dose intravenous steroids, then surgery should be seriously considered and it is certainly advisable if there has been no improvement within 3–5 days. Regular and joint review by gastroenterologist and surgeon is essential to identify patients who are failing to make anticipated progress and to ensure that surgery is neither inappropriately delayed nor undertaken. Some gastroenterologists will use azathioprine, cyclosporin A or infliximab in severe attacks to try and induce remission.

Indications for surgery

The greatest likelihood of a patient with UC requiring surgery is during the first year after diagnosis. The overall risk of colectomy is 20 per cent. Indications for surgery in UC are:

Figure 69.6 Abdominal radiograph demonstrating gas in the wall of the caecum (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

- severe or fulminating disease failing to respond to medical therapy;
- chronic disease with anaemia, frequent stools, urgency and tenesmus;
- steroid-dependent disease (here, the disease is not severe, but remission cannot be maintained without substantial doses of steroids);
- inability of the patient to tolerate medical therapy required to control the disease (steroid psychosis or other side effects, azathioprine-induced pancreatitis), such that remission cannot be maintained;
- neoplastic change: patients who have severe dysplasia or carcinoma on review colonoscopy;
- extraintestinal manifestations;
- rarely, severe haemorrhage or stenosis causing obstruction.

Operative treatment for UC

Emergency

In the emergency situation (or for a patient who is malnourished or on steroids), the 'first aid procedure' is a subtotal colectomy and end ileostomy. The rectal stump (really rectosigmoid) is left long and can either be brought out as a mucous fistula or closed just beneath the skin. Ideally, the rectal stump is exteriorised as a mucous fistula in the left iliac fossa, and not through the lower end of the wound, which creates significant problems for stoma management. This operation has the advantages that the patient avoids a pelvic operation while unstable, that colonic histology can be assessed and restorative surgery can be contemplated at a later date when the patient is no longer on steroids and has fully recovered from systemic illness and is optimally nourished. The operation is performed in a similar manner to an extended right hemicolectomy – the omentum should be preserved if possible and the dissection of the left colon is continued to divide the sigmoid at a level which will comfortably reach the skin as a mucous fistula. In colitis, it is not necessary to take the mesenteric vessels at their origin. Unless the rectosigmoid is itself disintegrating, the temptation to close the rectal stump and leave it stapled off in the pelvis should be avoided if at all possible. The diseased rectum may disintegrate, causing a pelvic abscess and severe sepsis, with potentially fatal consequences. Allowing the rectal remnant to discharge through the mucous fistula not only minimises the risk of this serious complication, but may also allow the delivery of high-dose topical steroid or 5-ASA compound, via the mucous fistula, into the isolated rectum.

Elective surgery

The indications for elective surgery include:

- failure of medical therapy/steroid dependence;
- growth retardation in the young;
- extraintestinal disease (polyarthropathy and pyoderma gangrenosum respond to colectomy);
- malignant change.

In the elective setting, four operations are available:

- 1 Subtotal colectomy and ileostomy (as in an emergency)
- 2 Proctocolectomy and permanent end ileostomy
- 3 Restorative proctocolectomy with ileoanal pouch
- 4 Subtotal colectomy and ileorectal anastomosis.

Segmental resections are not recommended as even when the right side is not obviously involved, there is a high recurrence rate in the remaining colon. Subtotal colectomy with ileostomy is performed electively for a frail patient, a patient who cannot be weaned from steroids and when there is doubt as to whether the colitis may represent Crohn's disease. A pouch, a completion proctectomy and even an ileorectal anastomosis can all then be considered at a future date. All of these procedures including formation of a pouch, can be performed laparoscopically in experienced hands.

Proctocolectomy and ileostomy

This operation removes all the colon and rectum, removing any risk of colorectal neoplasia or colitic symptoms, but it leaves a permanent stoma. It has a lower complication rate compared with a pouch procedure, although the perineal wound can be problematic (10 per cent fail to heal) and stoma problems are common. It is indicated for patients who are not candidates for restorative surgery due to sphincter problems or patient preference. The colectomy is performed as above. Provided there is no concern around rectal cancer a close rectal dissection may be performed to minimise damage to the pelvic nerves, avoiding erectile and bladder dysfunction. An intersphincteric excision of the anus is undertaken, which results in a smaller perineal wound and fewer healing problems. A permanent end ileostomy is formed, as described later, with scrupulous attention to detail to ensure a good functional and cosmetic result. It is particularly important to ensure that an adequate spout is created and the stoma is sited adequately to ensure that it is appropriate for the patient's build. The position of the ileostomy should be carefully chosen by the patient with the help of a stoma care nurse specialist. There is an argument for making the trephine incision before entering the abdomen to prevent any problems of distortion of the abdominal wall after opening. If performed laparoscopically, the specimen is removed through the perineal wound and so there is no requirement for any abdominal incision other than the port sites.

Restorative proctocolectomy with an ileoanal pouch (Parks)

In this operation, a pouch is made out of ileum (Figure 69.7) as a substitute for the rectum and sewn or stapled to the anal canal. This avoids a permanent stoma. It is reserved for patients with adequate anal sphincters and should be avoided when Crohn's disease is a possibility. Various pouch designs have been described, but the 'J' is the most popular and the most easily made using staplers (Figure 69.8). The 'S' (three loop) has been associated with evacuation difficulties due to the short efferent spout. The 'W' (four loop) pouch has a larger reservoir, which results in less bowel frequency. There is some controversy over the correct technique for ileoanal anastomosis. In the earliest operations, the mucosa from the dentate line up to midrectum was stripped off the underlying muscle, but it is now known that a long muscle cuff is not needed. Although mucosectomy of the upper anal canal with an anastomosis at the dentate line is claimed to remove all of the at-risk mucosa and any problem of subsequent cancer, it may also increase the risk of incontinence with nocturnal seepage. The alternative is an anastomosis double-stapled to the top of the anal canal, preserving the upper anal canal

Figure 69.7 Ileoanal anastomosis with pouch. A substitute rectum is made from joined folds of ileum to form an expanded pouch of small intestine. The pouch is then joined directly to the anus at the level of the dentate line, all other rectal mucosa having been removed. Three ways of forming a pouch are illustrated: (a) a simple reversed 'J'; (b) an 'S' pouch; (c) a 'W' pouch.

mucosa. Continence appears to be better, but there is a theoretical risk of leaving inflamed mucosa behind. The procedure can be carried out in stages. In most cases, a covering loop ileostomy is used as described later.

Complications include pelvic sepsis (usually resulting from a leak at the ileoanal anastomosis or, in a J pouch, from the top of the 'J'), postoperative small bowel obstruction (which may occur in as many as 10–15 per cent of patients) and pouch vaginal fistula. Frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but is typically between three and eight evacuations in each 24-hour period. Increased frequency, urgency and faecal incontinence can be seen (20, 5 and 5 per cent, respectively), but these reduce with time. Approximately 50 per cent of patients with ileoanal pouches have a very good quality of life, whereas 35 per cent of patients are less satisfied but choose to retain their pouches. Pouch function is so poor in 15 per cent that the pouch is removed. The main reasons for failure are pelvic sepsis (50 per cent), poor function (30 per cent)

Figure 69.8 Stapled 'J' pouch with stapler creating a pouch–anus anastomosis.

and pouchitis or inflammation of the pouch (10 per cent). It is also important for women of reproductive age to be advised that they may suffer from reduced fertility, as well as vaginal dryness, due to denervation of the secretory glands of the vaginal mucosa. Women who have not completed their families may elect for a colectomy with ileostomy and a pouch later. If it turns out that the patient actually has Crohn's disease, there is a high rate of pouch failure and the operation is not usually recommended in this disease.

In expert hands, a restorative proctocolectomy can be performed safely laparoscopically. This has a longer operative time but is likely to result in shorter lengths of stay. In young patients, the better cosmetic result with preservation of body image is a consideration. Striking images of well patients with tiny laparoscopic scars and no stoma can act as an advert for the laparoscopic approach. There is also the as yet unproven possibility that laparoscopic pouch surgery will result in a reduction in incisional hernias and small bowel obstruction and less effect on female fertility than open surgery. The key factors still to be determined for the laparoscopic approach are functional outcomes as there is a significant technical challenge to cross-stapling at the pelvic floor and there is the potential to leave a longer rectal cuff, than via an open approach, although this might be circumvented by a new perineal approach dubbed the APPEAR technique.

Pouchitis describes an inflammatory condition, which may affect 30 per cent of patients with an ileoanal pouch. It is characterised not only by the presence of inflammation in the pouch (which is common and frequently asymptomatic), but also by symptoms of pouch dysfunction (increased frequency, tenesmus, bleeding, purulent discharge) and systemic illness (malaise,

fever, raised inflammatory markers). The cause of pouchitis is unknown, but it appears to relate to inflammatory bowel disease (pouchitis does not seem to occur in pouches created for patients for other indications). Alterations in bacteria flora in the pouch may be relevant as pouchitis usually responds to a short course of antibiotic therapy, notably with metronidazole or ciprofloxacin.

Colectomy and ileorectal anastomosis

This procedure is occasionally performed in UC if there is minimal rectal inflammation after total colectomy. It is rarely appropriate as a very considerable percentage (at least 50 per cent) of patients with a quiescent rectum after total colectomy will develop significant mucosal inflammation in the rectum, once the faecal stream has been re-established. Although rectal inflammation can be controlled with medical treatment, functional results may be disappointing. If the rectum is preserved, then annual rectal inspection is advocated. Although this procedure has the advantage of avoiding a stoma and the risk to sexual function associated with rectal dissection, it has fallen out of favour due to the ongoing risk of persisting inflammation and malignancy in the retained rectum.

INDETERMINATE COLITIS

Ten per cent of patients with colitis present with histological features that make their disease difficult to characterise. They may, for example, have a patchy colitis, with evidence of fissuring and/or transmural ulceration, or cobblestoning of the colonic mucosa, raising the possibility of Crohn's disease, but without clear pathognomonic features of Crohn's disease, such as epithelioid granulomata (see below); such patients may be said to have an 'indeterminate colitis'. Indeterminate colitis is not, therefore, a specific disease entity so much as an indication by a pathologist that the underlying pattern of colitis (and therefore the course of the illness) is unclear. While the clinical history may suggest the diagnosis in some cases (for example, a history of recurrent perianal sepsis and fistulation would make a diagnosis of Crohn's disease more likely), in others, it may remain, despite colectomy, unclear whether a patient has UC or Crohn's disease. In such cases, it may still be appropriate to offer a pouch, but the risks of pouch failure appear to be significantly higher (up to 25–30 per cent) and patients should be advised accordingly.

CROHN'S DISEASE (REGIONAL ENTERITIS)

The label 'Crohn's disease' became attached to a chronic inflammatory disease of the ileum following a key publication by Burrill Crohn and colleagues in 1932. CD is characterised by a chronic full thickness inflammatory process that can affect any part of the gastrointestinal tract from the lips to the anal margin. It is most common in North America and Northern Europe with an incidence of 5 per 100 000. Prevalence rates of around 50 per 100 000 have been reported in the UK. Over the last four decades, there seems to have been a rise in the incidence, which

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer described regional ileitis in 1932.

cannot be accounted for by increased diagnosis. It is slightly more common in women than in men, and is most commonly diagnosed in young patients between the ages of 25 and 40 years. There does, however, seem to be a second peak of incidence around the age of 70 years. In those countries with high prevalence of CD, the groups with the highest prevalence seem to be Caucasian, notably American Whites and Northern Europeans, whereas it is less common, even in high prevalence countries, in those originating from Central Europe and less prevalent still in those originating from South America, Asia and Africa. CD seems to be especially prevalent (three- to five-fold higher) in the Ashkenazi Jewish population, although interestingly, the prevalence of CD in the Jewish population in Israel is lower than that in Europe or the United States, suggesting the importance of environmental factors.

Aetiology

The aetiology of Crohn's disease is incompletely understood but is thought to involve a complex interplay of genetic and environmental factors. Although CD shares some features with chronic infection, no causative organism has ever been demonstrated. An intriguing similarity to Johne's disease of cattle, a chronic inflammatory enteropathy resulting from infection with *Mycobacterium paratuberculosis*, suggests that CD in man may share a common aetiology. Some studies in which molecular biological analyses of tissue affected by CD have identified mycobacterial DNA more frequently in patients with CD than in controls, but others have been less conclusive and, in particular, randomised controlled trials have failed to show a significant therapeutic benefit of treating CD with antituberculous drugs. A wide variety of foods have been implicated, and in particular, a diet high in refined foodstuffs, but none conclusively. An association with high levels of sanitation in childhood has been suggested. Smoking increases the relative risk of CD three-fold and is certainly an exacerbating factor after diagnosis, contrary to the protective effect seen in UC. Genetic factors are clearly important. Approximately 10 per cent of patients have a first-degree relative with the disease, and concordance has been shown to approach 50 per cent in monozygotic twins. Inheritance is thought to involve multiple genes with low penetrance. The *NOD2/CARD15* gene has excited particular interest as variants of this gene have been shown to have strong associations with CD. Genetic manipulation of these genes in mice seems to induce the development of a disease resembling CD and abnormalities of these genes have been shown to be present in some members of families with a particularly high incidence of CD. It should be noted, however, that abnormalities of these genes have not been found in the vast majority of individuals with CD. Since these genes are involved in intracellular recognition of bacteria, their discovery provides potentially valuable insight into the pathogenesis of CD, as a disease in which the relationship between the gut mucosa and the normal gut bacteria becomes deranged, resulting in uncontrolled intestinal inflammation.

Pathogenesis

As in UC, there is thought to be an increased permeability of the mucous membrane. This may lead to increased passage of luminal antigens, which then induce a cell-mediated inflam-

matory response. This results in the release of proinflammatory cytokines, such as interleukin-2 and tumour necrosis factor, which coordinate local and systemic inflammatory responses. It has been suggested that CD is associated with a defect in suppressor T cells, which usually act to prevent escalation of the inflammatory process. As in UC, however, it remains unclear whether the proposed increase in intestinal permeability is a cause or consequence of the disease process. Studies of intestinal permeability in healthy and apparently unaffected first degree relatives of patients with CD have also, however, suggested that gut permeability is increased, suggesting that a global, and potentially genetically determined increase in gut permeability, combined perhaps with an abnormal immune-mediated response to colonisation of the gut with subspecies of the normal enteric microflora, may initiate the disease.

Pathology

The terminal ileum is most commonly involved (60 per cent), either in isolation or in combination with colonic disease. Colitis alone occurs in up to a third of cases and the remainder are patients with more proximal small bowel involvement. The stomach and duodenum are affected in around 5 per cent, but perianal lesions are common, affecting up to 50–75 per cent of patients. Perianal disease occurs in 25 per cent of patients with small bowel disease, but in 75 per cent of patients with Crohn's colitis.

Macroscopically, resection specimens show a fibrotic thickening of the intestinal wall with a narrow lumen and fat wrapping (encroachment of mesenteric fat around the bowel, Figure 69.9). There is usually dilated bowel just proximal to the stricture and deep mucosal ulcerations with linear or snake-like patterns in the strictured area itself. Oedema in the mucosa between the ulcers gives rise to a cobblestone appearance. The transmural inflammation (which is a key feature of CD) may lead to segments of bowel becoming adherent to each other and to surrounding structures, inflammatory masses with mesenteric abscesses and fistulae into adjacent organs. The serosa is usually opaque, with thickening of the mesentery and enlarged

Figure 69.9 Crohn's disease of the ileocaecal region showing typical thickening of the wall of the terminal ileum with narrowing of the lumen (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

mesenteric lymph nodes. CD is characteristically discontinuous, with inflamed areas separated from normal intestine, so-called 'skip' lesions.

Microscopically, there are focal areas of chronic inflammation involving all layers of the intestinal wall with lymphoid aggregates. Non-caseating giant cell granulomas are found in 60 per cent of patients and clearly define Crohn's disease. They are most common in anorectal disease. Multifocal arterial occlusions are found in the muscularis propria, which is thickened. There is deep, fissuring ulceration within affected areas. Characteristically, and unlike in UC, there may be completely normal areas immediately next to areas of severe inflammation.

Clinical features

Presentation depends upon the pattern of disease. Very infrequently, CD presents acutely with acute ileal inflammation and symptoms and signs resembling those of acute appendicitis, or even free perforation of the small intestine, resulting in a local or diffuse peritonitis. CD may present with fulminant colitis but this is considerably less common than in UC (see Summary box 69.4).

Summary box 69.4

Differences between ulcerative colitis and Crohn's disease

- Ulcerative colitis affects the colon; Crohn's disease can affect any part of the gastrointestinal tract, but particularly the small and large bowel
- UC is a mucosal disease, whereas CD affects the full thickness of the bowel wall
- UC produces confluent disease in the colon and rectum, whereas CD is characterised by skip lesions
- CD more commonly causes stricturing and fistulation
- Granulomas may be found on histology in CD, but not in UC
- CD is often associated with perianal disease, whereas this is unusual in UC
- CD affecting the terminal ileum may produce symptoms mimicking appendicitis, but this does not occur in UC
- Resection of the colon and rectum cures the patient with UC, whereas recurrence is common after resection in CD

Crohn's disease more commonly presents with features of chronicity. Chronic small bowel CD often manifests as mild diarrhoea extending over many months, occurring in bouts accompanied by intestinal colic. Patients may complain of pain, particularly in the right iliac fossa, and a tender mass may be palpable. Intermittent fevers, secondary anaemia and weight loss are common. After months of repeated attacks with acute inflammation, the affected area of intestine begins to narrow with fibrosis, causing obstructive symptoms. Children developing the illness before puberty may have retarded growth and sexual development. With progression of the disease, adhesions and transmural fissuring, intra-abdominal abscesses and fistula tracts may develop.

Fistulation may occur into adjacent loops of bowel (entero-enteric fistulae), and, most notably the (healthy) sigmoid loop may become adherent to the affected terminal ileum, resulting in ileosigmoid fistulation and profuse diarrhoea. Fistulation may

also occur into the bladder (ileovesical) or the female genital tract and, less commonly, the duodenum. Fistulation into the abdominal wall (enterocutaneous fistulation) may also develop spontaneously, but more commonly occurs as a complication of abdominal surgery.

Colonic CD presents with symptoms of colitis and proctitis as described for UC, although toxic megacolon is much less common (Figure 69.10).

Many patients with CD present with perianal problems. In the presence of active disease, the perianal skin appears bluish. Superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae, discharging around the anus and sometimes forwards into the genitalia. Fistulation through the posterior wall of the vagina may lead to rectovaginal fistula and continuous leakage of gas and/or faeces per vagina.

The rectal mucosa is often spared and may feel normal on rectal examination. If it is involved however, it will feel thickened, nodular and irregular. Perianal disease is frequently associated with dense, fibrous stricturing at the anorectal junction. Incontinence may develop as a result of destruction of the anal sphincter musculature because of inflammation, abscess formation, fibrotic change and repeated episodes of surgical drainage. In severe cases, the perineum may become densely fibrotic, rigid and covered with multiple discharging openings (watering-can perineum).

Extraintestinal manifestations

The extraintestinal manifestations of Crohn's disease are similar to those that occur in UC and are outlined in Summary box 69.5. Gallstones are common due to an inflamed or excised terminal ileum leading to reduced absorption of bile salts. Amyloidosis is common at post-mortem, but is rarely symptomatic. 'Metastatic' CD can occur in the vagina or skin with nodular ulcers, which demonstrate non-caseating granulomas when biopsied. The appearances can be indistinguishable macroscopically from hidradenitis suppurativa.

Figure 69.10 Colonic Crohn's disease. Note the normal mucosa on either side of the inflammatory stricture (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

Summary box 69.5**Extraintestinal manifestations of Crohn's disease**

- Related to disease activity
 - Erythema nodosum
 - Pyoderma gangrenosum
 - Arthropathy
 - Eye complications (iritis/uveitis)
 - Aphthous ulceration
 - Amyloidosis
- Unrelated to disease activity
 - Gallstones
 - Renal calculi
 - Primary sclerosing cholangitis
 - Chronic active hepatitis
 - Sacroiliitis

Investigations*Laboratory*

A full blood count should be performed, as anaemia is common and usually multifactorial, it may result from the anaemia of chronic disease, or from iron deficiency as a result of blood loss or malabsorption. Vitamin B12 deficiency may occur as a consequence of terminal ileal disease or resection. Active inflammatory disease is usually associated with a fall in serum albumin, magnesium, zinc and selenium. Acute phase protein measurements (C-reactive protein and orosomucoid) may correlate with disease activity.

Endoscopy

Colonoscopic examination may be normal or show patchy inflammation. There will be areas of normal colon or rectum in between areas of inflamed mucosa that are irregular and ulcerated, with a mucopurulent exudate. The earliest appearances are aphthous ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. There may be stricturing, and it is important to exclude malignancy in these sites. An irregular Crohn's stricture with polypoid mucosa may be almost indistinguishable from malignancy. The terminal ileum may be ulcerated and strictured. In patients who have had previous ileocaecal resection, recurrent disease usually presents first with aphthous ulceration proximal to the anastomosis.

Upper gastrointestinal symptoms may require upper gastrointestinal endoscopy, which may reveal deep longitudinal ulcers and cobblestone mucosa in the duodenum, stomach or, rarely, in the oesophagus. Enteroscopy may reveal jejunal ulceration and stricturing. Capsule endoscopy should not be undertaken where there is a risk of stricture, because of the possibility of the capsule becoming stuck in the narrow segment. It may, however, have a useful role in those patients with evidence of chronic gastrointestinal blood loss where no evidence of ulceration can be found with more conventional endoscopic assessment.

Imaging

High-resolution ultrasound in expert hands can demonstrate inflamed and thickened bowel loops, as well as fluid collections and abscesses. The small intestine is traditionally imaged by a

small bowel enema (Figure 69.11). This will show up areas of stricturing and prestenotic dilatation. The involved areas tend to be narrowed, irregular and, sometimes, when a length of terminal ileum is involved, there may be the string sign of Kantor. CT scans with luminal contrast are widely used in the investigation of abdominal symptoms and can demonstrate fistulae, intra-abdominal abscesses and bowel thickening or dilatation (Figure 69.12). Magnetic resonance imaging (MRI) is useful in assessing complex perianal disease, but more recently has been shown to be an excellent method for investigating the small bowel. MR enteroclysis is particularly effective at demonstrating small bowel stricturing (Figure 69.13) and avoids the need for repeated exposure to large doses of ionising radiation in young patients. In patients with enterocutaneous fistulae, fistulography will be required to demonstrate the anatomy and complexity of fistulae and allow adequate planning for future surgery.

TREATMENT**Medical treatment***Steroids*

Steroids are the mainstay of treatment for CD. They induce remission in 70–80 per cent of cases with moderate to severe disease. They should be used in short courses and tapered after response has been achieved. They reduce inflammation and will not therefore be effective against fibrostenotic disease, where the symptoms relate mainly to obstruction. Steroids can also be used as topical agents in the rectum with reduced sys-

Figure 69.11 Small bowel enema examination showing a narrowed terminal ileum involved with Crohn's disease – the 'string' sign of Kantor.

temic bioavailability, but long-term use can still cause adrenal suppression. More recent oral steroid formulations have been devised to ensure that the steroid moiety is removed from the portal circulation, reducing systemic side effects. Steroids should not be used for maintenance therapy for CD and are usually replaced with immunomodulatory agents (see below under Immunomodulatory agents) in order to minimise the risk of side effects associated with long-term steroid use.

Aminosalicylates

Colonic symptoms can be treated by 5-ASA agents in a similar manner to that in UC. These agents have been traditionally believed to help with management of small bowel CD, but this has recently been questioned. Some studies of patients who have undergone previous resection have suggested that 5-ASA drugs may reduce the incidence of recrudescence disease.

Antibiotics

Metronidazole and ciprofloxacin may be used, particularly for periods of a few weeks at a time, especially in perianal disease. Long-term use of metronidazole is to be especially avoided, as there is a risk of peripheral neuropathy. Antibiotics may also be used when there is evidence of a mass or an abscess. In general, however, a confirmed abscess should be treated by drainage plus or minus resection as antibiotics alone will not treat a Crohn's mass effectively.

Immunomodulatory agents

Azathioprine is used for its additive and steroid-sparing effect and is now standard maintenance therapy. It is a purine analogue, which is metabolised to 6-mercaptopurine (6-MP) and works by inhibiting cell-mediated immune responses. 6-Mercaptopurine may be given directly for the same reasons. Cyclosporin also acts by inhibiting cell-mediated immunity. Short-course intravenous cyclosporin treatment is associated with 80 per cent remission; however, there is relapse after completion of treatment.

Monoclonal antibody

Several commercially available agents have been developed based upon monoclonal antibodies targeting tumour necrosis factor alpha. Infliximab, the murine chimaeric monoclonal antibody and Adalimumab (human monoclonal) are used for patients with severe, active disease who are refractory to other forms of treatment and who would otherwise be at high risk of requiring surgical intervention. There is some evidence to suggest that early and aggressive use of these agents in patients with evidence of early recrudescence disease after surgery (for example, by colonoscopy showing aphthous ulceration at the anastomosis at one year) may reduce the need for subsequent surgery. These agents also appear to be effective treatments for fistulae, particularly in perianal disease. Recent studies have suggested, however, that they reduce the inflammation associated with the process of fistulation and that the fistula tracks may remain unhealed, even if the skin defects close. Cessation of therapy is associated with a high risk of reactivation of the fistulae. These are very expensive forms of treatment and active infection, tuberculosis and a past history of malignancy are contraindications.

Nutritional support

It is essential that nutritional status is evaluated in all patients with CD. Nutritional support is frequently required. Patients with moderate nutritional impairment will require nutritional supplementation and severely malnourished patients may require nasoenteric or even intravenous feeding. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. Elemental diet or parenteral nutrition can induce remission in up to 80 per cent of patients, an effect comparable to steroids. Almost all patients relapse rapidly after cessation of therapy (Summary box 69.6).

Non-operative management of Crohn's disease

Although perforating and fistulating disease will require surgical treatment (see below under Surgery), stricturing may be amenable to endoscopic treatment, provided the strictures can be reached with an endoscope and negotiated with a guide

Summary box 69.6**Principles of management of Crohn's disease**

- Close liaison between physician and surgeon is crucial
- Medical therapy should always be considered as an alternative to surgery, although surgery should not be delayed when a clear indication for surgery exists
- Patients must be optimised as far as possible prior to surgery, and this may require preoperative total parenteral nutrition
- Crohn's disease is a chronic relapsing disease with a high likelihood of reoperation; the surgeon must take every reasonable effort to preserve bowel length and sphincter function

wire. This may be accomplished by enteroscopy or colonoscopy, depending upon the site of the stricture. Dilatation of an inflamed and ulcerated stricture is contraindicated because of the risks of perforation, but balloon dilatation of fibrostenotic disease may result in substantial symptomatic improvement and obviate the need for surgery in selected cases.

Indications for surgery

Surgical resection will not cure CD. Surgery therefore focuses on the complications of the disease. As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is thought to be ideal (see Figure 69.6). These complications include:

- recurrent intestinal obstruction
- bleeding
- perforation
- failure of medical therapy
- intestinal fistula
- fulminant colitis
- malignant change
- perianal disease.

Surgery

The main surgical principle is to preserve gut length and maintain adequate function. The whole of the gastrointestinal tract should be examined carefully at laparotomy/laparoscopy and intestinal resection kept to the minimum required to treat the local consequences of disease. If, on occasion, CD is diagnosed during the course of an operation for suspected appendicitis, it is reasonable to remove the appendix, although there may be concern about fistulation. If the ileum is thick, rigid and inflamed, an ileocaecal resection can be carried out immediately, although it is equally reasonable to try a period of medical therapy. A senior opinion is important to determine the optimum therapy, taking into account the patient's history, fitness, comorbidity and operative findings.

The course of the disease after surgery is unpredictable, but recrudescence (a better term than 'recurrence' as surgery cannot cure) is common. Symptomatic recrudescence does not seem to be related to the presence of disease at the resection line. The cumulative probability of recrudescence requiring surgery for ileal disease is of the order of 20, 40, 60 and 80 per cent at 5, 10, 15 and 20 years, respectively, after previous resection.

Crohn's surgery is technically demanding as mesenteries are thickened and oedematous, the bowel may be fragile and the

patient may be malnourished, immunosuppressed or septic. A key decision has to be made after resection between anastomosis and defunctioning, as leaks and fistulation are a notorious problem. It has been established that anastomotic complications are more common with one or more of the following risk factors:

- steroids
- low albumin
- abscess
- fistula.

If more than two factors are present it is safer (and if all, imperative) to exteriorise the bowel and consider delayed anastomosis when the patient has fully recovered.

Laparoscopic surgery is possible for ileocaecal or colonic resections and has the potential advantage of smaller incisions and potentially shorter recovery time. Reoperative surgery is technically demanding but experienced laparoscopic surgeons have been able to carry out such procedures. A great range of operations is performed for Crohn's disease depending on disease pattern – the most common are outlined below:

- Ileocaecal resection is the usual procedure for terminal ileal Crohn's with a primary anastomosis between the ileum and the ascending or transverse colon, depending on the extent of the disease.
- Segmental resection of short segments of small or large bowel strictures can be performed.
- Colectomy and ileorectal anastomosis is commonly performed for colonic CD with rectal sparing and a normal anus.
- Subtotal colectomy and ileostomy for Crohn's colitis accounts for 8 per cent of such procedures for acute colonic disease. The indications are similar to those for UC.
- Temporary loop ileostomy. This can be used either in patients with acute distal CD, allowing remission and later restoration of continuity, or in patients with severe perianal or rectal disease.
- Proctocolectomy. Patients with colonic and anal disease failing to respond to medical treatment will eventually require a permanent ileostomy.
- Strictureplasty. Multiple strictured areas of CD (Figure 69.14) can be treated by a local widening procedure, strictureplasty, to avoid small bowel resection (Figure 69.15).

Figure 69.14 Small bowel strictures in Crohn's disease with dilatation between strictures.

Figure 69.15 Strictureplasty. (1) A strictured length of intestine is incised along its length. (2) The bowel is opened and the walls are retracted as shown. (3) The bowel is resutured transversely to widen the narrowed segment.

- Anal disease should be treated conservatively to avoid sphincter injury by simple drainage of abscesses and the use of setons through fistulae.

INFECTIONS OF THE SMALL AND LARGE INTESTINE

Campylobacter

Infection with *Campylobacter jejuni* (a Gram-negative rod with a distinctive spiral shape) is the most common form of gastroenteritis in the UK, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain and may mimic an acute abdomen. Severe cases may resemble UC and cause diagnostic difficulty. The organism is very sensitive and may take several days to isolate on stool culture. Treatment is supportive as it usually resolves without antibiotics. It is a notifiable disease.

Yersinia

Yersinia enterocolitica is a Gram-negative rod, which can infect the terminal ileum, appendix, ascending colon and mesenteric lymph nodes, and can cause a granulomatous inflammatory process that mimics Crohn's disease. *Yersinia* typically causes a fever and gastroenteritis, but may persist and cause a terminal ileitis, which, on occasion, may even perforate. The diagnosis may be made on stool culture, but is more often confirmed serologically. If discovered at laparotomy, the terminal ileum and mesenteric nodes will look thickened and inflamed and a lymph node biopsy can be taken. The disease is normally self-limiting, but also responds to treatment with co-trimoxazole or chloramphenicol.

Intestinal amoebiasis

Amoebiasis is an infestation with *Entamoeba histolytica*. This parasite has a worldwide distribution and is transmitted mainly in contaminated drinking water. It can cause colonic ulcers, which are described as 'bottlenecked' because they have considerably undermined edges. The ulcers typically also have a yellow necrotic floor, from which blood and pus exude. In the majority of cases, they are confined to the distal sigmoid colon and the rectum.

Clinically amoebiasis can mimic UC, most commonly causing bloody diarrhoea but more severe colonic complications can occur, including severe haemorrhage, stricture formation or perforation. A pericolicitis is not uncommon and results in adhesions and may cause intestinal obstruction. Amoebiasis may cause liver abscesses or an amoebic mass (amoeboma) of the caecum or sigmoid which is difficult to distinguish from a carcinoma. Surgery is fraught with danger as the bowel is extremely friable.

Endoscopic biopsies or fresh hot stools are examined to look for the presence of amoebae (Figure 69.16). It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic. It is especially important to exclude amoebic infection in patients suspected of having UC.

Treatment is by metronidazole (Flagyl) in the acute setting, three times daily for 7–10 days. Diloxanide furoate is effective against chronic infections associated with the passage of cysts in stools.

Salmonellosis, typhoid and paratyphoid

Salmonella are a family of Gram-negative rods that can cause a range of enteric infections. *Salmonella* gastroenteritis is typically caused by *S. enteritidis* from poultry, and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics and indeed hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. *Shigella* and enteropathogenic strains of *E. coli* may cause similar diarrhoeal illnesses.

Typhoid fever is caused by *S. typhi* and presents with fever and abdominal pain after an incubation period of 10–20 days. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic 'rose spots' on the abdomen caused by a vasculitis. A number of surgical complications can result:

- paralytic ileus
- intestinal haemorrhage
- perforation
- cholecystitis.

In addition, invasion of the systemic circulation, which is a characteristic feature of salmonellosis, may cause severe Gram-negative sepsis and septic shock may develop. Some patients develop metastatic sepsis, including septic arthritis and osteomyelitis, meningitis, encephalitis, disseminated intravascular coagulation and pancreatitis.

Figure 69.16 An amoeba in a rectal biopsy.

Perforation of a typhoid ulcer usually occurs during the third week and is sometimes the first sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the distal ileum. Diagnosis is confirmed by culture of blood or stool. Treatment is by antibiotics, usually chloramphenicol. Perforation requires surgery to wash out and close the perforated ulcer – resection is usually avoided. In unstable patients, notably with evidence of septic shock, the bowel should be exteriorised and the perforation closed after recovery. Paratyphoid infection (with *S. paratyphi*) resembles typhoid fever and is treated in a similar manner.

Tuberculosis of the intestine

Tuberculosis, like Crohn's disease, can affect any part of the gastrointestinal tract from the mouth to the anus. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal presentations.

Ulcerative tuberculosis

Ulcerative tuberculosis is secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. Multiple ulcers, lying transversely, develop in the terminal ileum and the overlying serosa is thickened, reddened and covered in tubercles. Patients typically present with diarrhoea and weight loss, although subacute obstruction and even local perforation and fistula formation can occur. A barium follow-through or CT examination show absent filling of the lower ileum, caecum and the ascending colon as a result of narrowing of the ulcerated segment (Figure 69.17).

A course of chemotherapy (antituberculous antibiotics) usually leads to cure, provided the pulmonary tuberculosis is adequately treated. Surgery is usually undertaken only in the rare event of a perforation or complete intestinal obstruction.

Hyperplastic tuberculosis

This is caused by the ingestion of *Mycobacterium tuberculosis* by patients with a high resistance to the organism. The infection usually occurs in the ileocaecal region, although solitary and multiple lesions in the lower ileum are also sometimes seen. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes, which may caseate. Unlike in Crohn's disease, abscess and fistula formation is rare.

Patients usually present with attacks of abdominal pain and intermittent diarrhoea. There is incomplete ileal obstruction, leading to stasis and bacterial overgrowth. This in turn causes steatorrhoea, anaemia and loss of weight. Patients may present with a mass in the right iliac fossa and vague ill health. The differential diagnosis is that of an appendix mass, lymphoma, carcinoma of the caecum, CD, tuberculosis or actinomycosis.

A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum. CT will also demonstrate the narrowed segment with proximal distension and can also demonstrate the lymphadenopathy. When the diagnosis is certain and the patient has not yet developed obstructive symptoms, treatment with chemotherapy is advised and may be curative. Where obstruction is present, surgery with ileocaecal resection is often required.

Figure 69.17 Ileocaecal tuberculosis; absent ascending colon and caecum with dilatation of terminal ileum (courtesy of Dr VK Kapoor, Delhi, India).

Actinomycosis

Abdominal actinomycosis is rare. It is caused by infection with *Actinomyces israelii* and infection usually develops several weeks after an apparently straightforward perforated appendicitis. A local abscess develops and spreads to the retroperitoneal tissues and the adjacent abdominal wall, becoming the seat of multiple indurated discharging sinuses. At first, the discharge from the sinuses is thin, watery and inoffensive, but it may later become thicker and malodorous. Secondary fistulation may occur and the tissues may become extensively indurated and woody. In contrast to tuberculosis, however, mesenteric lymph nodes are not involved and the lumen of the intestine is not narrowed. Haematogenous spread via the portal vein may lead to multiple liver abscesses.

Pus should be sent for bacteriological examination, which will reveal the characteristic sulphur granules. Penicillin or cotrimoxazole treatment should be prolonged and in high dosage.

Human immunodeficiency virus

Human immunodeficiency virus (HIV) infection is associated with a number of proctological problems as discussed in Chapter 73. Intestinal complications are common after the development of AIDS when opportunistic organisms can cause gastroenteritis (see Summary box 69.7). HIV1 may also cause a specific enter-

opathy. Treatment is directed towards the responsible organism and surgery should be avoided.

Summary box 69.7

Opportunistic intestinal infections in patients with AIDS

- Bacteria
 - Salmonella
 - Shigella
 - Yersinia
 - Campylobacter
 - Mycobacterium avium intracellulare* (MAI)
- Viral
 - Cytomegalovirus
- Protozoa
 - Cryptosporidium
 - Giardia
- Fungal
 - Candida albicans*

Clostridium difficile

Clostridium difficile is a toxin producing Gram-positive bacillus that is an increasing worry in many hospitals. Although normally present in around 2 per cent of the population, it seems to proliferate after antibiotic treatment (especially cephalosporins) and can cause antibiotic-associated diarrhoea and pseudomembranous colitis.

Clinically, *C. difficile* infection presents with diarrhoea, abdominal pain and fever. It may progress to pseudomembranous colitis, so called because on visualisation of the bowel, plaques of inflammatory exudate between oedematous mucosa are seen.

Treatment is by metronidazole or vancomycin alongside supportive care. If the colitis does not settle, an emergency subtotal colectomy and ileostomy may be necessary.

TUMOURS OF THE SMALL INTESTINE

Small bowel tumours are rare and in total account for less than 10 per cent of gastrointestinal neoplasia.

Benign

The majority of small bowel neoplasms are benign, comprising adenomas, lipomas, haemangiomas and neurogenic tumours. They are frequently asymptomatic and identified incidentally, but can present with intussusception, small bowel obstruction and bleeding that may cause anaemia or may even be overt. Where these lesions do cause anaemia, the cause can be difficult to diagnose, as CT or small bowel contrast studies do not show them easily. Capsule endoscopy or small bowel endoscopy have been used successfully where the facilities exist. Symptomatic lesions can be treated by small bowel resection and anastomosis.

Peutz-Jeghers syndrome

This is an autosomal dominant disease characterised by melanosis of the mouth and lips and multiple hamartomatous (benign tumour-like malformation resulting from faulty development in an organ) polyps in the small bowel and colon (Figure 69.18).

Figure 69.18 Melanin spots on the lips of a patient afflicted with Peutz-Jeghers syndrome (courtesy of Major PCM Manta, Indian Medical Service).

Melanin spots can also occur on the digits and perianal skin. The gene *STK11* on chromosome 19 has been found in a proportion of patients with this condition. Long-term follow up of the original family described by Peutz has shown reduced survival, as a consequence of complications of bowel obstruction and the development of a wide range of cancers. It is logical to perform regular colonic surveillance and encourage female patients to attend breast and cervical screening.

Malignant change in the polyps rarely occurs and, in general the polyps can be left alone. Resection may be indicated for heavy and persistent or recurrent bleeding or intussusception. Polyps may be removed by enterotomy, or, at laparotomy, snared via a colonoscope introduced via an enterotomy. Heavily involved segments of small intestine may occasionally be resected.

Malignant

These are rare and classically present late, most often diagnosed after surgery for small bowel obstruction. Four types will be considered which account for over 99 per cent of small bowel malignancies: adenocarcinoma, carcinoid tumours, lymphomas and mesenchymal tumours (gastrointestinal stromal tumours (GIST)).

Gregor Johann Mendel, 1822–1884, an Austrian monk and naturalist who became Abbot of the Augustinian Monastery at Brunn, Czechoslovakia and discovered the laws of inheritance by studying the edible pea. In 1865, he described 'dominant' and 'recessive' traits in hybrids. His work passed unnoticed for 35 years.

Adenocarcinoma

Small bowel adenocarcinoma is more often found in the jejunum than the ileum and though the aetiology is unknown they are more common in patients with Crohn's disease, coeliac disease, familial adenomatous polyposis (FAP) and Peutz-Jeghers syndrome. They present with anaemia, overt gastrointestinal bleeding, intussusception or obstruction. Prognosis is poor, particularly in patients with Crohn's disease, in whom these tumours often present late because the symptoms may be mistaken for those of Crohn's disease and treated conservatively. When suspected, the advised surgical treatment is a resection of 5 cm of non-involved bowel either side of the lesion and the affected mesentery (Figure 69.19). A right hemicolectomy is likely to be required for tumours of the distal ileum.

Carcinoid tumour

These neuroendocrine tumours occur throughout the gastrointestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. Appendicular carcinoid tumours are most commonly noted as an incidental finding at appendicectomy. Carcinoid tumours arise from Kulchitsky cells at the base of intestinal crypts (of Lieberkuhn). The primary is usually small, although significant lymph node metastases can occur. In up to one in three cases of small bowel carcinoids, the tumours may be multiple. They may produce dense fibrosis in the surrounding tissues, resulting in distortion and scarring of the bowel and associated mesentery.

The tumours can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), but also histamine, prostaglandins and kallikrein. When they metastasise to the liver, the carcinoid syndrome can become evident, because the vasoactive substances escape the filtering actions of the liver. The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, pulmonary and tricuspid stenosis (Summary box 69.8). Classically, the flushing attacks are induced by alcohol.

Surgical resection is usually sufficient for patients with primary disease, but the incidence of recurrence is significant. The extent of disease can be assessed preoperatively using octreotide scanning, which may detect otherwise clinically apparent primary and secondary tumours. Plasma markers of tumour bulk,

Summary box 69.8

Carcinoid syndrome

- Diarrhoea
- Bronchospasm
- Facial/upper chest flushing
- Palpitations
- Tricuspid regurgitation

such as chromogranin A concentrations, may be useful markers of disease recurrence, as well as of prognostic value.

In patients with metastatic disease, hepatic resection can be carried out. The treatment has been transformed by the use of octreotide (a somatostatin analogue), which reduces both flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis. Carcinoid tumours generally grow more slowly than most metastatic malignancies; the patients may live with the syndrome of metastatic disease for many years. They are not usually sensitive to chemo- or radiotherapy.

Lymphoma

Small bowel lymphoma may be primary, or more commonly secondary to systemic lymphoma. Small bowel lymphoma is also more common in patients with Crohn's disease and immunodeficiency syndromes. The classification of lymphoma is beyond the scope of this chapter, however a number of points are notable for the surgeon. It is rare for Hodgkin's lymphoma to affect the small bowel and most western-type lymphomas are non-Hodgkin's B-cell lymphomas. They present with anaemia, bleeding, perforation, anorexia and weight loss.

T-cell lymphoma develops in patients with coeliac disease. Worsening of the patient's diarrhoea, with pyrexia of unknown origin together with local obstructive symptoms, are the usual features.

Mediterranean lymphoma is found mostly in North Africa and the Middle East and is often widespread at diagnosis. Burkitt's lymphoma can aggressively affect the ileocaecal region, particularly in children. The mainstay of treatment for these conditions is chemotherapy, however surgery may be required for obstruction, perforation or bleeding.

Gastrointestinal stromal tumours

These are mesenchymal tumours and the distinction between benign or malignant types is difficult even on histological examination. Increased size and high levels of c-kit (CD117) staining are associated with malignant potential. GIST tumours are found most commonly in the stomach, but can be found in other parts of the gut. They occur most commonly in the 50- to 70-year age group. Although the cause is unknown, patients with neurofibromatosis have an increased risk of developing these types of tumour.

Patients may be asymptomatic. Symptoms include lethargy, pain, nausea, haematemesis or melaena. Surgery is the most effective way of removing GISTs, as they are radioresistant. Glivec (imatinib) is a tyrosine kinase inhibitor that has been shown to be effective in advanced cases and may also have an adjuvant role.

Figure 69.19 Small bowel adenocarcinoma.

TUMOURS OF THE LARGE INTESTINE

Benign

The term 'polyp' is a clinical description of any protrusion of the mucosa. It encompasses a variety of histologically different tumours shown in Table 69.2. Polyps can occur singly, synchronously in small numbers or as part of a polyposis syndrome. It is important to be sure of the histological diagnosis because colonic adenomas have significant malignant potential.

Adenomatous polyps

Adenomatous polyps vary from a tubular adenoma (Figure 69.20), rather like a berry on a stalk, to the villous adenoma, a flat spreading lesion. Solitary adenomas are usually found during the investigation of colonic symptoms and may be the cause of rectal bleeding. Villous tumours can cause diarrhoea, mucous discharge and, occasionally, hypokalaemia and hypoalbuminaemia. The risk of malignancy developing in an adenoma increases with their size; there is a 10 per cent risk

of cancer in a 1-cm diameter tubular adenoma, whereas with villous adenomas over 2 cm in diameter, there may be a 15 per cent chance of carcinoma. Almost one-third of large (>3 cm) colonic adenomas will have an area of invasive malignancy within them at the time of resection. Adenomas larger than 5 mm in diameter are usually excised because of their malignant potential. Colonoscopic snare polypectomy is usually possible for colonic polyps, but larger sessile polyps can require endoscopic mucosal resection (EMR) after saline infiltration. Larger rectal adenomas may require transanal resection or, where the adenoma is too high for safe conventional access, transanal endoscopic microsurgery (TEMS). Massive and extensive villous lesions of the rectum may require proctectomy when the patient is sufficiently fit, or argon beam ablation when the patient is frail but symptomatic.

Familial adenomatous polyposis

FAP is defined clinically by the presence of more than 100 colorectal adenomas, but also characterised by duodenal adenomas and multiple extraintestinal manifestations (Summary box 69.9). Over 80 per cent of cases come from patients with a positive family history. The remainder arise as a result of new mutations in the adenomatous polyposis coli (APC) gene. This has been identified on the short arm of chromosome 5. FAP is inherited as an autosomal dominant condition and is consequently equally likely in men and women. Although FAP is less common than hereditary non-polyposis colon cancer (HNPCC), and only accounts for 1 per cent or less of all colon cancer, the risk of colorectal cancer is 100 per cent in patients with FAP. FAP can also be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner's syndrome); desmoid tumours in the abdomen spread locally to involve the intestinal mesentery and, although non-metastasising, they can become unresectable. Up to 50 per cent of patients with FAP have congenital hypertrophy of the retinal pigment epithelium (CHRPE), which can be used to screen affected families if genetic testing is unavailable.

Table 69.2 Classification of intestinal polyps.

Classification		
Inflammatory	Inflammatory polyps (pseudopolyps in ulcerative colitis)	
Metaplastic	Metaplastic or hyperplastic polyps	
Harmartomatous	Peutz-Jeghers polyp Juvenile polyp	
Neoplastic	Adenoma	Tubular
		Tubulovillous
		Villous
	Adenocarcinoma Carcinoid tumour

Summary box 69.9

Extracolonic manifestations of familial adenomatous polyposis

- Endodermal derivatives
 - Adenomas and carcinomas of the duodenum, stomach, small intestine, thyroid and biliary tree
 - Fundic gland polyps
 - Hepatoblastoma
- Ectodermal derivatives
 - Epidermoid cysts
 - Pilomatrixoma
 - Congenital hypertrophy of the retinal pigment epithelium (CHRPE)
 - Brain tumours
- Mesodermal derivatives
 - Desmoid tumours
 - Osteomas
 - Dental problems

Clinical features

Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30 years. Carcinoma of the large bowel occurs 10–20 years after the onset of the polyposis. One or more cancers will already be present in two-thirds of those patients presenting with symptoms at the time of diagnosis (see Summary box 69.10).

Summary box 69.10

Features of familial adenomatous polyposis

- Autosomal dominant inherited disease due to mutation of the APC gene
- More than 100 colonic adenomas are diagnostic
- Prophylactic surgery is indicated to prevent colorectal cancer
- Polyps and malignant tumours can develop in the duodenum and small bowel

Symptomatic patients

These are either patients in whom a new mutation has occurred or those from an affected family who have not been screened. They may have loose stools, lower abdominal pain, weight loss, diarrhoea and the passage of blood and mucus. Colonoscopy is performed with biopsies to establish the number and histological type of polyps. If over 100 adenomas (Figure 69.21) are present, the diagnosis can be made confidently. If there are no adenomas by the age of 30 years, FAP is unlikely. If the diagnosis is made during adolescence, operation is usually deferred to the age of 17 or 18 years unless symptoms develop.

Screening policy

- At-risk family members are offered genetic testing in their early teens.
- At-risk members of the family should be examined at the age of 10–12 years, repeated every year.
- Most of those who are going to get polyps will have them at 20 years, and these require operation.
- If there are no polyps at 20 years, continue with five-yearly examination until age 50 years; if there are still no

Figure 69.21 Familial adenomatous polyposis.

polyps, there is probably no inherited gene. Carcinomatous change may exceptionally occur before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential, and a family tree should be constructed and a register of affected families maintained. Referral to a medical geneticist is essential.

Treatment

The aim of surgery is to prevent the development of colorectal cancer. The surgical options are:

- colectomy with ileorectal anastomosis (IRA);
- restorative proctocolectomy (RPC) with an ileal pouch-anal anastomosis, the anastomosis may be defunctioned with a loop ileostomy;
- total proctectomy and end ileostomy (normally reserved for patients with a low rectal cancer).

The patient is almost always young and likely to prefer to avoid a permanent stoma and so the choice is normally between the first two options. The advantage of an IRA is that it avoids the temporary stoma frequently required for an RPC and avoids the potential compromise to sexual function that accompanies proctectomy. It also has a lower morbidity and mortality. However, the rectum is left and requires regular surveillance, as there is a risk of adenomas and carcinomas in the residual large bowel. Even with optimal surveillance of the rectal remnant, up to 10 per cent will develop invasive malignancy within a 30-year follow-up period. Restorative proctocolectomy has the advantage of removing the whole colon and rectum (although a small cuff of rectal mucosa may be left behind with a stapled anastomosis). However, there is a pouch failure rate of about 10 per cent. In addition, and particularly where a stapled anastomosis has been created, there remains a very small but definite incidence of cancer developing in the small strip of rectal mucosa between the pouch and the dentate line. This is why some colorectal surgeons advocate complete mucosectomy of the residual rectal cuff and a transanal pouch anal anastomosis, although it is acknowledged that this results in worse function.

Postoperative surveillance

Because of the risk of further tumour formation, follow up is important and takes the form of rectal/pouch surveillance, with biopsy of the pouch-anal anastomosis. Gastrosopies are also carried out to detect upper gastrointestinal tumours. Even with prevention of colorectal cancer, FAP patients have reduced life span due to the development of duodenal and ampullary cancers and the complications of desmoid tumours.

Hereditary non-polyposis colorectal cancer (Lynch syndrome)

This syndrome is characterised by increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestines. It is an autosomal dominant condition that is caused by a mutation in one of the DNA mismatch repair genes. The most commonly affected genes are *MLH1* and *MSH2*. The lifetime risk of developing colorectal cancer in Lynch syndrome is 80 per cent, and the mean age of diagnosis is 45 years. Most cancers develop in the proximal colon. Females with HNPCC have a 30–50 per cent lifetime risk of developing endometrial cancer.

Diagnosis

HNPCC can be diagnosed by genetic testing or the Amsterdam II criteria:

- three or more family members with an HNPCC-related cancer (colorectal, endometrial, small bowel, ureter, renal pelvis), one of whom is a first-degree relative of the other two;
- two successive affected generations;
- at least one colorectal cancer diagnosed before the age of 50 years;
- FAP excluded;
- tumours verified by pathological examination.

Patients with HNPCC are subjected to regular (every one to two years) colonoscopic surveillance.

Malignant

Epidemiology

In the UK, colorectal cancer is the second most common cause of cancer death accounting for 16 000 deaths in 2004. About 35 000 patients are diagnosed with colorectal cancer every year in the UK, of which around one-third are in the rectum and two-thirds in the colon. The burden of disease is similar in men and women. Colorectal cancer seems to occur less frequently in the developing world than in industrialised countries.

Aetiology

The accepted model of colorectal cancer development is that it arises from adenomatous polyps after a sequence of genetic mutations influenced by environmental factors. This adenoma–carcinoma sequence is based on strong observational evidence outlined in Summary box 69.11.

Summary box 69.11

Evidence for adenoma–carcinoma sequence

- The prevalence of adenomas and carcinomas is very similar – carcinoma patients are about five years older
- The distribution of adenomas in the colon is the same as that of cancers (70 per cent left sided)
- When small cancers are studied, they almost always have adjacent adenomatous tissue
- Adenomas are found in a third of specimens resected for colorectal cancer
- Sporadic adenomas are identical to the adenomas of familial adenomatous polyposis, which is associated with a 100 per cent chance of colorectal adenocarcinoma unless treated
- Larger adenomas are more likely to be dysplastic and to have higher grades of dysplasia than small adenomas.
- Incidence of colorectal cancer falls within a screening programme that involves colonoscopy and polypectomy

The molecular genetics of sporadic colorectal cancer have been extensively studied. Mutations of the APC gene occur in two-thirds of colonic adenomas and carcinomas and are thought to develop early in the carcinogenesis pathway. K-ras mutations result in activation of cell signalling pathways and are more common in larger lesions. This suggests that they are later events in the mutagenesis pathway. The *p53* gene is frequently mutated in carcinomas, but not in adenomas and is

therefore thought to mark the development of invasion. The adenoma–carcinoma sequence is not, however, one of a simple stepwise progression of mutations, but a complicated array of multiple genetic alterations, ultimately resulting in an invasive tumour. While no single mutation is common to all cases of colorectal cancer, knowledge of certain mutations can be used to assess prognosis and, increasingly to direct adjuvant therapy. For example, the K-ras mutation is thought to be associated with an especially poor prognosis.

There has been much interest in the linkage between diet and colon cancer. Worldwide, the prevalence of colorectal cancer is closely associated with intake of red meat. There is ample evidence to suggest effects of red meat components (haem and N-nitroso compounds) on the DNA in the colorectal mucosa. The protective effect of dietary fibre is also suggested by epidemiological studies. The hypothesis is that increased roughage is associated with reduced transit times, and this in turn reduces the exposure of the mucosa to dietary carcinogens. Increased risk for colorectal cancer has also been associated with dietary animal fat, smoking and alcohol. Longstanding ulcerative colitis and Crohn's colitis is associated with increased rates of colorectal cancer as discussed previously. It has been suggested that cholecystectomy may be associated with a slight increase in the risk of right-sided colon cancer, possibly as a consequence of increased bile acid exposure. There is also an increased risk of colorectal cancer after ureterosigmoidostomy, although this procedure is now rarely performed.

Pathology

Macroscopically, the tumour may take one of four forms (Figure 69.22). The annular variety tends to give rise to obstructive symptoms, whereas the others will present more commonly with

Figure 69.22 The four common macroscopic varieties of carcinoma of the colon. (1) Annular; (2) tubular; (3) ulcer; (4) cauliflower.

bleeding. Microscopically, the neoplasm is an adenocarcinoma originating in the colonic epithelium.

SPREAD OF CARCINOMA OF THE COLON

Direct spread

Colonic cancer can spread locally or via the lymphatics, blood-stream or transcoelomically around the peritoneum. Direct spread can be longitudinal, transverse or radial. Radial spread to adjacent organs has the greatest impact on surgical resectability, as an adequate oncologic resection can still be achieved, despite longitudinal spread, by extension of proximal and distal margins. Radial spread may be retroperitoneal into the ureter, duodenum and posterior abdominal wall muscles, or intraperitoneal into the small intestine, stomach, pelvic organs or the anterior abdominal wall.

Lymphatic spread

In general, involvement of the lymph nodes by the tumour progresses in a gradual manner from those closest to the bowel along the course of the lymphatic vessels to those placed centrally. However, this orderly process does not always occur.

Haematogenous spread

The liver accounts for the majority of distant metastases presumably via the portal vein. Around a third of patients will have liver metastases at the time of diagnosis and 50 per cent will develop liver metastases at some point accounting for the majority of deaths. The lung is the next most common site: metastases to ovary, brain, kidney, brain and bone are less common. Occasionally, patients will present with metastatic disease in the lungs without evidence of liver metastases.

Transcoelomic spread

Colorectal cancer can spread by way of cells dislodging from the serosa of the bowel or via the subperitoneal lymphatics and settling on other structures within the peritoneal cavity, including peritoneum and omentum. Prognosis is typically grave in these circumstances although some units have reported encouraging results in selected patients treated with the combination of aggressive cytoreductive surgery and intraperitoneal chemotherapy.

Staging colon cancer

A variety of staging systems are described for colorectal cancer based on pathological reporting to predict prognosis and guide adjuvant treatment. Dukes' classification was originally described for rectal tumours (see Chapter 72), but has been adopted for histopathological reporting of colon cancer as well. It is simple and widely recognised (Summary box 69.12), but the more detailed TNM system is now regarded as the international standard (Summary box 69.13).

Rupert B Turnbull, 1913–1981, Irish surgeon, Cleveland Clinic, Ohio, reported the presence of cancer cells in the portal vein of patients undergoing resection for colon cancer. He then described in his Moynihan lecture a 'no touch' isolation technique to reduce the manipulation of colonic tumours at surgery.

Summary box 69.12

Dukes' staging for colorectal cancer

- A, Invasion of but not breaching the muscularis propria
- B, Breaching the muscularis propria but not involving lymph nodes
- C, Lymph nodes involved

Dukes himself never described a stage D, but this is often used to describe metastatic disease

Summary box 69.13

TNM classification for colonic cancer

- **T**, Tumour stage
 - T1, Into submucosa
 - T2, Into muscularis propria
 - T3, Into pericolic fat or sub-serosa but not breaching serosa
 - T4, Breaches serosa or directly involving another organ
- **N**, Nodal stage
 - N0, No nodes involved
 - N1, 1–3 nodes involved
 - N2, Four or more nodes involved
- **M**, Metastases
 - M0, No metastases
 - M1, Metastases

Clinical features

Carcinoma of the colon typically occurs in patients over 50 years of age and is most common in the eighth decade of life. Colorectal cancer is not rare in early adult life, however. Twenty per cent of cases present as an emergency with intestinal obstruction or peritonitis. An emergency presentation of colorectal cancer is, even when matched for disease stage, associated with a considerably worse prognosis. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer at the age of 45 years or below are at higher risk and may be part of one of the colorectal cancer familial syndromes. Tumours of the left side of the colon which are far more common (Figure 69.23) usually present with a change in bowel habit or rectal bleeding, while more proximal lesions typically present later with iron deficiency anaemia or a mass. Patients may present for the first time with metastatic disease. Lesions of the flexures may present with vague upper abdominal symptoms for many months before other, more specific symptoms suggestive of colonic disease appear.

St Mark's Hospital, Harrow, UK, is recognised as a national and international referral centre for intestinal and colorectal disorders. It was founded in a small room in No 11 Aldersgate Street. Established in 1854 on City Road in Hackney as St Mark's Hospital for Fistula and other Diseases of the Rectum. It was so named as it was opened on St Mark's day, April 25. In 1994, it moved to its present site in Harrow.

Cuthbert Esquire Dukes, 1890–1977, pathologist, St Mark's Hospital, London, UK. The original Dukes' classification in 1932 gave three stages, A–C.

Figure 69.23 Distribution of colorectal cancer by site.

Investigation of colon cancer

Screening

Colon cancer is highly suited to screening as prognosis is better for early stage disease and polypectomy allows the prevention of cancer development. In the UK, a screening programme has been introduced based on faecal occult blood testing of people aged 60–69 years followed by colonoscopy in those who test positive. A guaiac-based test is used which detects the peroxidase-like activity of faecal haematin. Studies have suggested a 15–20 per cent reduction in colorectal cancer mortality in the screened population. Flexible sigmoidoscopy can also be used as the initial screening tool with a similar reduction in colorectal cancer mortality.

Endoscopy

The 60-cm, fibreoptic, flexible sigmoidoscope is increasingly being used in one-stop rectal bleeding clinics. The patient is prepared with an enema and sedation is not usually necessary. It is usually possible to assess the bowel up to the splenic flexure, which will detect up to 70 per cent of cancers and almost all that cause rectal bleeding. Colonoscopy is the investigation of choice if colorectal cancer is suspected, provided the patient is fit enough to undergo the required mechanical bowel preparation (Figure 69.24). It has the advantage of not only picking up a primary cancer, but also having the ability to detect synchronous polyps or even multiple carcinomas, which occur in 3–5 per cent of cases. Ideally, every case should be proven

Figure 69.24 A cancer seen at colonoscopy.

histologically by biopsy before surgery. Full mechanical bowel preparation is necessary, as well as intravenous sedation. There is a small risk of perforation (1:1000) and also even experienced endoscopists may fail to see the caecum in 10 per cent of cases.

Radiology

Double-contrast barium enema shows a cancer of the colon as a constant irregular filling defect often described as looking like an apple core (Figure 69.25). False positives occur in 1–2 per cent of cases and false negatives in 7–9 per cent of cases. CT is used as a diagnostic tool in patients with palpable abdominal masses. Use of spiral CT of the chest and abdomen is now standard to stage colonic cancer by assessing T stage and detecting metastases although chest x-ray and liver ultrasound are an alternative if CT is not readily available. The introduction of CT virtual colonoscopy, which is effective in picking up polyps down to 6 mm (Figure 69.26) provides another diagnostic modality and has largely replaced barium enema in many centres. It has the advantage of being less invasive than colonoscopy, but if a biopsy is required, an endoscopy will still be needed.

Surgical treatment

Preoperative preparation

There is good evidence that there is no benefit for mechanical bowel preparation in colonic cancer surgery and it may in fact be associated with an increased rate of wound infection. Rectal cancer seems to be different and recent trials suggest that mechanical bowel preparation is probably still appropriate. Thromboembolism is common in general surgical patients and the risk is increased by malignant disease, so antiembolic stockings should be fitted and the patient started on prophylactic subcutaneous low molecular weight heparin. If available, manual compression boots can be used perioperatively. Intravenous prophylactic antibiotics are given at the start of surgery, as there is good evidence that these reduce the risk of

Figure 69.25 Barium enema showing a carcinoma of the sigmoid colon. It may have an 'apple core' appearance, i.e. a short, irregular stenosis with sharp shoulders at each end.

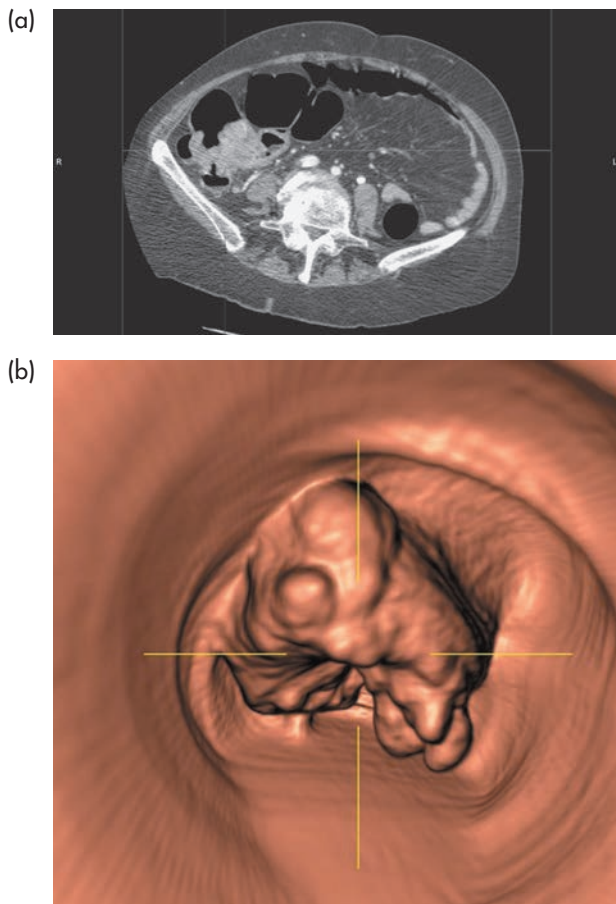

Figure 69.26 Virtual colonoscopy of the right colon. (a) Computed tomography scan of the abdomen showing a caecal tumour. (b) Formatted 'virtual' image of the same lesion as in (a) (courtesy of Dr A Slater, John Radcliffe Hospital, Oxford, UK).

would infection and sepsis. A single dose of antibiotics covering bowel organisms is as effective as multiple doses in preventing wound infection. In all cases where a stoma seems likely, careful preoperative counselling and marking of an appropriate site by an enterostomal therapist is essential.

Operations

The operations described are designed to remove the primary tumour and its draining locoregional lymph nodes. After spiral CT, it is unusual to find unsuspected metastases at laparotomy (or laparoscopy), but the presence of peritoneal metastases may predicate a palliative strategy with a segmental resection and less aggressive lymphadenectomy. The use of stapling and hand-suturing techniques for colonic anastomosis has been compared, and there is little difference in leak rate between the two. Recurrent disease does occur typically at the anastomosis and re-resection can be successful.

Right hemicolectomy

Carcinoma of the caecum or ascending colon (Figure 69.27) is treated when resectable by right hemicolectomy (Figure 69.28). At open surgery, the peritoneum lateral to the ascending colon is incised, and the incision is continued around the hepatic flexure. The right colon is elevated, with the leaf of perito-

Figure 69.27 Large villous tumour of the caecum with malignant change.

Figure 69.28 Schematic showing right hemicolectomy.

neum containing its vessels and lymph nodes, from the posterior abdominal wall, taking care not to injure the ureter, gonadal vessels or the duodenum. The ileocolic artery is ligated close to its origin off the superior mesenteric artery ('high-tie') and divided. Where the right colic artery has a separate origin from the superior mesenteric artery (around 10 per cent of patients), this is separately ligated. The leaf of raised peritoneum attached to the caecum, ascending colon and hepatic flexure is divided after ligation of the mesentery of the last 20 cm of ileum and the mesocolon as far as the proximal third of the transverse colon. The greater omentum is divided up to the point of intended division of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected, and an anastomosis is fashioned between the ileum and the transverse colon using the surgeon's preferred technique. If the tumour is at the hepatic flexure, the resection must be extended further along the transverse colon and will involve dividing the right branch of the middle colic artery.

Extended right hemicolectomy

Carcinomas of the transverse colon and splenic flexure are most commonly treated by an extended right hemicolectomy. The extent of the resection is from right colon to descending colon. The mobilisation is as for a right hemicolectomy, but dissection continues to take down the splenic flexure and the whole transverse mesocolon is ligated. Some surgeons will perform a left hemicolectomy for a splenic flexure cancer.

Left hemicolectomy

This is the operation of choice for descending colon and sigmoid cancers (Figure 69.29). The left half of the colon is mobilised completely along the 'white line' that marks the lateral attachment of the mesocolon. As the sigmoid mesentery is mobilised, the left ureter and gonads must be identified and protected. The splenic flexure must be mobilised by extending the dissection from below and from the transverse colon side by entering the lesser sac. The inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, are included in the resection by ligating the inferior mesenteric artery close to its origin – 'high-tie'. For full mobility, the inferior mesenteric vein is also ligated and divided at the lower border of the pancreas. The bowel and mesentery can now be resected to allow a tension-free anastomosis, which can be stapled with an end–end stapling device or hand-sewn. Where there are technical difficulties or concern about the anastomosis, a temporary diverting stoma may be fashioned upstream, usually by formation of a loop ileostomy.

Laparoscopic surgery

Laparoscopic surgery for colonic cancer has now been shown to have equivalent overall and cancer-related outcomes to open surgery. Lymph node harvests are equivalent to open surgery and initial concerns about reports of port site recurrence have been dispelled as the world experience has grown. In the UK, the National Institute for Health and Clinical Excellence (NICE) has endorsed laparoscopic colorectal surgery and has stated it should be offered to suitable patients. Operative times

are longer but wound infection rates, blood loss and postoperative pain scores are lower than for open surgery. It is hoped that these factors will lead to shorter hospital stay and faster return to full activity, but this has yet to be firmly demonstrated. The costs of laparoscopic surgery are generally higher and this may be particularly relevant where funds are limited.

It is not possible to palpate lesions, so if laparoscopic surgery is planned, it is ideal to tattoo the lesion. Different surgeons advocate different port positions. The laparoscopic operation has particular advantages if performed in a medial to lateral manner – that is, starting the dissection by controlling and dividing the major vascular pedicles and only taking the lateral peritoneal reflection once the mesocolon is completely free. Specimen retrieval and bowel anastomosis can then be performed via small incisions. Training in laparoscopic surgery is important, as there is a steep learning curve and in the UK is currently part of a national training programme.

Emergency surgery

In the UK, 20 per cent of patients with colonic cancer will present as an emergency, the majority with obstruction, but occasionally with haemorrhage or perforation. If the lesion is right sided, it is usually possible to perform a right hemicolectomy and anastomosis in the usual manner; this can be facilitated by decompressing the bowel at the start of the operation. If there has been perforation with substantial contamination or if the patient is unstable, it may be advisable to bring out an ileo/colostomy rather than anastomosing bowel in these circumstances. For a left-sided lesion, the decision-making process is similar to that in diverticular disease between a Hartmann's procedure and resection and anastomosis. Where facilities are present, an obstructing left-sided lesion can be treated with an expanding metal stent (Figure 69.30). This has the great advantage of converting an emergency operation with a high chance of a stoma to a situation which can be managed semi-electively with a resection and anastomosis. It is currently unclear whether

Figure 69.29 Schematic showing left hemicolectomy.

Figure 69.30 Abdominal radiograph demonstrating a colonic stent in position (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

the overall morbidity and mortality of staged management of an obstructing colorectal cancer by initial stenting and later surgery are lower than primary emergency surgery. Results from two European trials have so far failed to demonstrate a benefit and the patients in whom stenting proved impossible seemed to have a higher morbidity and mortality, possibly because of the inherent delay in undertaking definitive surgical treatment. A larger multicentre trial is currently in progress.

Postoperative care

After colonic surgery, patients should be closely monitored, as there is a small incidence of postoperative bleeding. Antithrombosis measures prophylaxis against venous thromboembolism should be continued as discussed above under Preoperative preparation. There is no advantage to placing intra-abdominal drains after colonic surgery. Wound infections are sadly common after colonic surgery and may well be more frequent than the quoted 10 per cent. The most feared postoperative complication of anastomotic breakdown or leak occurs in 4–8 per cent of ileocolic or colocolic anastomoses. It should be kept in mind for any patient not progressing as expected or who is developing temperatures and worsening abdominal pain. Early investigation with contrast-enhanced CT scan is appropriate. In the presence of sepsis or peritonitis, early return to theatre and taking down the leaking anastomosis with the formation of stomas is advised.

Traditional practices after bowel surgery were prolonged nasogastric drainage and very cautious introduction of oral fluid and then diet. There is increasing interest after bowel surgery in enhanced recovery programmes (ERPs) which have been shown to reduce length of hospital stay from the traditional 10–14 days, to as little as 2–3 days by modulating the surgical stress response and reducing postoperative ileus. It is important to appreciate that these programmes require multiple interventions to be instituted and considerable time, effort and education from the surgical, anaesthetic and ward teams (Summary box 69.14).

Summary box 69.14

Key elements of an enhanced recovery programme

- Pre-admission counselling
- Avoidance of mechanical bowel preparation
- Preoperative carbohydrate loading
- Avoidance of preoperative dehydration
- No nasogastric tubes
- Short, transverse incisions (or laparoscopic procedure)
- Short-acting anaesthetic drugs
- Avoidance of perioperative fluid/salt overload
- Thoracic epidurals
- Avoidance of opiate analgesia
- Maintenance of perioperative temperature
- Prevention of postoperative nausea and vomiting
- Early mobilisation
- Early introduction of oral fluids/diets/supplements
- Early removal of urinary catheters
- Continual audit of outcomes

Adjuvant therapy

This is discussed in more detail in Chapter 72 under rectal cancer. In colonic cancer, there is no current role for preoperative

chemotherapy although a trial is underway. There is evidence of improved outcome after surgery with 5-fluorouracil (5-FU)-based chemotherapy in node-positive disease (Dukes' C/N1,2).

Metastatic disease

Hepatic metastases can be resected and series have demonstrated five-year survival of over 30 per cent in resectable disease. Liver surgeons are increasingly aggressive in treatment and the only absolute limitation on what can be resected is in terms of leaving enough functional liver behind, although this clearly has to be moderated in terms of patient factors. It is important not to biopsy potentially resectable hepatic metastases as this may cause tumour dissemination. Imaging will usually correctly identify colorectal metastases and assess patients' suitability for liver resection (Figure 69.31). The role of chemotherapy and the timing of colonic and hepatic surgery in synchronous metastases is still a matter of debate and such cases should be carefully discussed by a multidisciplinary team. Isolated lung metastases may also in occasional cases be suitable for resection, but generally they are accompanied by metastases elsewhere. In patients with widespread disease, palliative chemotherapy can be offered alongside symptomatic treatment and support by a palliative care team.

Prognosis

Overall five-year survival for colorectal cancer is approximately 50 per cent. The most important determinant of prognosis is tumour stage and, in particular, lymph node status. Patients with disease confined to the bowel wall (Dukes' stage A) will

Figure 69.31 Computed tomography scan of the liver showing multiple metastases from carcinoma of the colon.

usually be cured by surgical resection alone and 90 per cent of such patients will have disease-free survival at five years. Spread beyond the bowel wall reduces five-year survival to approximately 60–70 per cent. Patients with lymph node metastases have a five-year survival of 30 per cent, while fewer than 10 per cent of patients presenting with metastatic disease at outset will be alive five years later.

Colorectal cancer follow up

Since the advent of safe liver resection for metastases, the outcome benefit of follow up has become evident and has been demonstrated by meta-analysis. Follow up aims to identify synchronous bowel tumours that were not picked up at original diagnosis due to emergency presentation or incomplete assessment (3 per cent of patients will have a second bowel cancer at diagnosis). Similarly, 3 per cent of patients will develop a metachronous (at a different time) colonic cancer and surveillance colonoscopy is designed to diagnose these. Up to a half of patients with colorectal cancer will have liver metastases at some point and regular imaging of the liver (ultrasound and CT scan) and measurement of carcinoembryonic antigen (CEA) is designed to diagnose this early, in order to allow the possibility of curative metastectomy. Trials of the optimum follow-up pathway are ongoing.

INTESTINAL DIVERTICULA

Diverticula (hollow out-pouchings) are a common structural abnormality that can occur from the oesophagus to the rectosigmoid junction (but not usually in the rectum). They can be classified as:

- **Congenital.** All three coats of the bowel are present in the wall of the diverticulum, e.g. Meckel's diverticulum.
- **Acquired.** There is no muscularis layer present in the diverticulum, e.g. sigmoid diverticula.

Jejunal diverticula

These arise from the mesenteric side of the bowel as a result of mucosal herniation at the point of entry of the blood vessels. They can vary in size and are often multiple. They are most often asymptomatic and an incidental finding at surgery or on radiological imaging (Figure 69.32); however, they can result in malabsorption, as a result of bacterial stasis, or present as an acute abdominal emergency if they become inflamed or perforate. Bleeding from a jejunal diverticulum is a rare complication. Elective resection of an affected small bowel segment that is causing malabsorption can be effective. If perforated jejunal diverticulitis is found at emergency laparotomy, a small bowel resection should be performed and a decision made between anastomosis and stoma formation. This will depend on degree of contamination, physiological stability and local resource for managing a patient with a high output jejunostomy. Extensive jejunal diverticulosis can be very difficult to treat. In severe cases, much of the proximal small intestine may be involved, effectively precluding resection. In addition, limited resection, while feasible, may fail to deal adequately with recurrent attacks of inflammation or bleeding.

Figure 69.32 Jejunal diverticula.

Meckel's diverticulum

A Meckel's diverticulum is a persistent remnant of the vitellointestinal duct and is present in about 2 per cent of the population. It is found on the antimesenteric side of the ileum, commonly at 60 cm from the ileocaecal valve and is classically 5 cm long (Figure 69.33). A Meckel's diverticulum contains all three coats of the bowel wall and has its own blood supply. It is vulnerable to obstruction and inflammation in the same way as the appendix; indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel's diverticulum should be looked for by examining the small bowel particularly if free fluid or pus is found (Summary box 69.15).

Figure 69.33 Meckel's diverticulum.

Summary box 69.15**Features of Meckel's diverticulum**

- Remnant of vitelointestinal duct
- Occurs in 2 per cent of patients, 2 inches (5 cm long), 2 feet (60 cm) from the ileocaecal valve, 20 per cent heterotopic epithelium
- Should be looked for when a normal appendix is found at surgery for suspected appendicitis
- If a Meckel's is found incidentally at surgery, it can be left provided it has a wide mouth and is not thickened
- Can be source of gastrointestinal bleeding if it contains ectopic gastric mucosa

In around 20 per cent of cases, the mucosa of a Meckel's diverticulum contains heterotopic epithelium of gastric, colonic or pancreatic type. A Meckel's diverticulum can present clinically in the following ways:

- **Haemorrhage.** If gastric mucosa is present, peptic ulceration can occur and present as painless maroon rectal bleeding or melaena. If the stomach, duodenum and colon are cleared by endoscopy, radioisotope scanning with technetium-99m may demonstrate a Meckel's. (A Meckel's is notoriously difficult to see with contrast radiology.)
- **Diverticulitis.** Meckel's diverticulitis presents like appendicitis, although if perforation occurs the presentation may resemble a perforated duodenal ulcer.
- **Intussusception.** A Meckel's can be the lead point for ileoileal or ileocolic intussusception.
- **Chronic ulceration.** Pain is felt around the umbilicus, as the site of the diverticulum is midgut in origin.
- **Intestinal obstruction.** A band between the apex of the diverticulum and the umbilicus (also part of the vitelointestinal duct) may cause obstruction directly or by a volvulus around it.
- **Perforation.** (Figure 69.34).

The vast majority of Meckel's are asymptomatic. When found in the course of abdominal surgery, a Meckel's can safely be left

alone provided it has a wide mouth and is not thickened. When there is doubt, it can be resected. The finding of a Meckel's diverticulum in an inguinal or femoral hernia has been described as Littre's hernia.

Meckel's diverticulectomy

A broad-based Meckel's diverticulum should not be amputated at its base and invaginated (as for an appendix), as there is the risk of stricture and of leaving heterotopic epithelium behind. It is safer simply to excise the diverticulum, either by resecting it and suturing the defect at its base, or with a linear stapler-cutter. If the base of the diverticulum is indurated, it is on balance more logical to perform a limited small bowel resection of the involved segment followed by an anastomosis.

Diverticular disease of the large intestine

Diverticula are found in the left colon in around 75 per cent of over 70 year olds in the Western world. The condition is overwhelmingly found in the sigmoid, but diverticula are found in the caecum and can affect the whole colon (but not the rectum). Interestingly, in South-East Asia, right-sided diverticular disease is more common. Diverticula are most often asymptomatic (diverticulosis) and found incidentally, but can present clinically with sepsis or haemorrhage.

Aetiology

Epidemiology supports the widely held view that diverticular disease is a consequence of a refined Western diet deficient in dietary fibre. The combination of altered collagen structure with ageing, disordered motility and increased intraluminal pressure most notably in the narrow sigmoid colon results in herniation of mucosa, protruding through the circular muscle at the points where blood vessels penetrate the bowel wall. The rectum has a complete muscular coat and a wider lumen and is thus very rarely affected. Diverticular disease is rare in Africa and Asia where the diet is high in natural fibre.

Complications of diverticular disease

The majority of patients with diverticula are asymptomatic; historical studies suggest somewhere between 10 and 30 per cent will have symptomatic complications (Summary box 69.16). These complications are:

- **Pain and inflammation (diverticulitis).**
- **Perforation:** most often contained leading to pericolic abscess formation, but occasionally free leading to generalised peritonitis.
- **Intestinal obstruction:** progressive fibrosis can cause stenosis of the sigmoid and large bowel obstruction or loops of small intestine can adhere to an inflamed sigmoid resulting in small bowel obstruction.
- **Haemorrhage:** diverticulitis may present with profuse colonic haemorrhage.
- **Fistula formation:** (colovesical, colovaginal, enterocolic, colocutaneous) occurs in 5 per cent of cases, colovesical fistulation is most common.

Figure 69.34 Gangrenous Meckel's diverticulitis.

Summary box 69.16**Complications of diverticular disease**

- Diverticulitis
- Abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

Clinical features

In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome. These symptoms are thought to result from a combination of increased luminal pressure affecting wall tension and increased visceral hypersensitivity. The difficulty in distinguishing between otherwise uncomplicated diverticular disease and irritable bowel syndrome is such that surgical treatment is rarely, if ever, appropriate for diverticular disease in the absence of complications.

Diverticulitis typically presents as persistent lower abdominal pain, usually in the left iliac fossa accompanied by loose stools or indeed constipation. Fever, malaise and leukocytosis can differentiate diverticulitis from painful diverticulosis. The lower abdomen is tender, especially on the left, but occasionally also in the right iliac fossa, if the sigmoid loop lies across the midline. The sigmoid colon may be tender and thickened on palpation and rectal examination may reveal a tender mass if an abscess has formed. Distinguishing between diverticulitis and abscess formation is difficult on clinical grounds alone and radiological imaging assessment is important. Generalised peritonitis as a result of free perforation presents in the typical manner with systemic upset and generalised tenderness, guarding and rebound. Similarly, large and/or small bowel obstruction due to diverticular disease has the same clinical features as other causes (see Chapter 69) and the aetiology is likely to be discovered only by imaging or at laparotomy.

Haemorrhage from colonic diverticula is typically painless and profuse. When from the sigmoid, it will be bright red with clots, whereas right-sided bleeding will be darker. Torrential bleeding is fortunately rare and in fact more commonly due to angiodysplasia but diverticular bleeding may persist or recur requiring transfusion and indeed resection. The presentation of a fistula resulting from diverticular disease depends on the site. The most common colovesical fistula results in recurrent urinary tract infections and pneumaturia (flatus in the urine) or even faeces in the urine. Colovaginal fistulae are more common in patients who have had a hysterectomy. Colocutaneous fistulation is rare in the absence of prior intervention (e.g. radiological drainage). Rarely, diverticular disease may perforate into the retroperitoneum leading to a psoas abscess, and then presenting in the groin with fistulation.

Classification of contamination

The degree of sepsis has a major impact on outcome in acute diverticulitis. Those with inflammatory masses have a lower mortality than those with perforation (3 versus 33 per cent).

Classification systems have been developed for acute diverticulitis to try and rationalise the literature, the most commonly used is the Hinchey classification (Table 69.3).

Table 69.3 Hinchey classification of complicated diverticulitis.

Grade	
I	Mesenteric or pericolic abscess
II	Pelvic abscess
III	Purulent peritonitis
IV	Faecal peritonitis

Radiology

Plain chest and abdominal radiographs can demonstrate a pneumoperitoneum. Where available, spiral CT has excellent sensitivity and specificity for identifying bowel wall thickening, abscess formation and extraluminal disease and has revolutionised the assessment of complicated diverticular disease (Figure 69.35). On identification of abscesses in stable patients, drainage may be carried out percutaneously, avoiding the need for laparotomy/laparoscopy. If access to CT is limited, a water-soluble contrast enema can demonstrate intraluminal inflammation and contrast extravasation. This investigation also has a role in large bowel obstruction to distinguish mechanical blockage from pseudo-obstruction, however distinguishing between a malignant and a diverticular stricture may be difficult.

Barium enemas (and colonoscopy/flexible sigmoidoscopy) are usually avoided in the acute setting for fear of causing perforation or peritonitis. However, they are used after an attack has settled to exclude a coexisting carcinoma and assess

Figure 69.35 Computed tomographic scan demonstrating an abscess associated with diverticulitis (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

the extent of diverticular disease (Figure 69.36). Colovesical fistulae should be evaluated with cystoscopy and biopsy in addition. Contrast examinations or CT may demonstrate the fistula clearly. The differential diagnosis for colovesical fistula includes cancer, radiation injury, Crohn's disease, tuberculosis and actinomycosis.

Colonoscopy

Colonoscopy is normally deferred until 6 weeks after an acute attack of diverticulitis. It may demonstrate the necks of diverticula within the bowel lumen (Figure 69.37). A narrowed area of diverticular disease may be impassable because of the severity of disease and there is a significant risk of endoscopic perforation. Colonoscopy in these circumstances requires judgement and experience. The differential diagnosis from a carcinoma can be impossible if a tight stenosis prevents colonoscopy. Biopsies may be taken if possible and corroboration with barium enema or CT virtual colonoscopy is required.

Management

Patients are frequently recommended to take a high-fibre diet and bulk-forming laxatives, although the evidence for the effectiveness of these in diverticulosis or after an attack of diverticulitis is limited. Antispasmodics may have a role if recurrent pain is a problem. Acute diverticulitis is treated by intravenous antibiotics (to cover Gram-negative bacilli and anaerobes) alongside appropriate resuscitation and analgesia. Nil by mouth to 'rest the bowel' and catheterisation to reduce the risk of colovesical fistulation are often advocated, but there is little evidence to support these practices. A CT scan can confirm the diagnosis and assess for complications. After the acute attack

Figure 69.36 Barium enema showing sigmoid diverticular disease 'saw-teeth' and diverticula (courtesy of Dr D Nolan, John Radcliffe Hospital, Oxford, UK).

Figure 69.37 Colonoscopic view of sigmoid diverticula. Note the mouths of diverticula between the hypertrophied colonic walls.

has subsided and if CT has not already confirmed the diagnosis, the bowel should be investigated by endoscopy, barium enema or CT virtual colonoscopy. An abscess can be drained percutaneously, 5 cm is frequently regarded as a cut off between an abscess likely to settle with antibiotics and one likely to require intervention.

Operative procedures for diverticular disease

The aim of emergency surgery is to control peritoneal sepsis; indications are generalised peritonitis and failure to respond to best medical management (Summary box 69.17). Laparotomy for diverticular disease in the acute setting has considerable risk with mortality in most series around 15 per cent and in the case of faecal peritonitis mortality approaches 50 per cent. Alongside operative technique, resuscitation, anaesthesia and postoperative management should be optimised.

Summary box 69.17

Principles of surgical management of diverticular disease

- Hartmann's procedure is the safest option in emergency surgery
- Primary anastomosis can be considered in selected patients
- Elective resection may be offered for recurrent attacks
- Definitive treatment of colovesical fistula will require resection

It is logical to perform a rigid sigmoidoscopy to avoid missing a rectal carcinoma. Laparotomy and thorough washout of contamination are performed and then a choice has to be made between a Hartmann's procedure (sigmoid resection with formation of left iliac fossa colostomy and closure of the rectal stump) and resection with colonic washout and anastomosis (\pm defunctioning loop ileostomy). Primary anastomosis should be used selectively but is appealing in a young fit patient without

gross contamination or overwhelming sepsis. However, this is a relatively rare scenario and the majority of emergency operations for perforated diverticular disease are Hartmann's procedures (Figure 69.38). There is good evidence that simple defunctioning with a proximal stoma is associated with higher mortality than a resection. There may be an emerging role for emergency laparoscopy in diverticular disease with washout if there is no faecal contamination (i.e. Hinchey grade III or less), avoiding sigmoid resection. At present, this remains in the domain of the experienced laparoscopic surgeon.

Indications for surgery in an elective setting are controversial. There are undoubtedly a small number of patients with recurrent attacks who should be offered an elective sigmoid colectomy (with anastomosis). This could be performed laparoscopically in experienced hands with a likely but not clearly proven swifter recovery, as well as improved cosmesis. Cohort series studies suggest that of younger patients (under 50 years old) admitted with diverticulitis, 25 per cent will get a further episode. This is used as an argument for offering elective resection, but equally suggests 75 per cent will not have another severe attack. Many surgeons would discuss the pros and cons of elective surgery after two emergency admissions, although general health must be carefully considered. There has been an increasing tendency, in recent years, to treat even patients with recurrent attacks of diverticulitis conservatively in the absence of complications.

Figure 69.38 (a) Perforated sigmoid diverticular disease. (b) The Hartmann procedure – oversewn rectal stump and left iliac fossa colostomy.

Diverticular fistulae can only be cured by resection of the affected bowel, although a defunctioning stoma can ameliorate symptoms. In the most common scenario of a colovesical fistula, the sigmoid can often be pinched off the bladder and the sigmoid resected. If an anastomosis is performed, it is wise to place an omental pedicle to prevent recurrent fistulation. There will be occasions when a bladder resection is required and it is ideal to involve a urologist or general surgeon experienced in bladder surgery.

Haemorrhage from diverticular disease should be distinguished from angiodysplasia. It usually responds to conservative management and only occasionally requires resection. Where available angiography is helpful to localise bleeding points. On-table lavage and colonoscopy may be necessary to localise the bleeding site. If the source cannot be located, then subtotal colectomy and ileostomy is the safest option.

VASCULAR ANOMALIES OF THE INTESTINE

Mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whereas emboli lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent because of a better collateral circulation.

Possible sources for the embolisation of the SMA include a left atrium associated with fibrillation, a mural myocardial infarction, an atheromatous plaque from an aortic aneurysm and a mitral valve vegetation associated with endocarditis.

Primary thrombosis is associated with atherosclerosis and thromboangitis obliterans. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden, portal hypertension, portal pyaemia and sickle cell disease and in women taking the contraceptive pill.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is the only layer of the intestinal wall to have little resistance to ischaemic injury. The intestine and its mesentery become swollen and oedematous. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. If the main trunk of the SMA is involved, the infarction covers an area from just distal to the duodenojejunal flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is less.

Clinical features

The most important clue to an early diagnosis of acute mesenteric ischaemia is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically central and out of all proportion to physical findings. Persistent vomiting and defaecation occur early, with the subsequent passage of altered blood. Hypovolaemic shock rapidly ensues. Abdominal tenderness may be mild initially with rigidity being a late feature.

Investigation will usually reveal a profound neutrophil leucocytosis with an absence of gas in the thickened small intestine on abdominal radiographs. The presence of gas bubbles in the mesenteric veins is rare but pathognomonic.

Treatment needs to be tailored to the individual. In conjunction with full resuscitation, embolectomy via the ileocolic artery or revascularisation of the SMA may be considered in early embolic cases. The majority of cases, however, are diagnosed late. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable. Anticoagulation should be implemented early in the postoperative period.

After extensive enterectomy, it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation.

Infarction of the large intestine alone is relatively rare. Involvement of the middle colic artery territory should be treated by transverse colectomy and exteriorisation of both ends, with an extended right hemicolectomy in selected cases.

Ischaemic colitis describes the structural changes that occur in the colon as a result of the deprivation of blood. They are most common in the splenic flexure, whose blood supply is particularly tenuous. They have been classified by Marston into gangrenous, transient and stricturing forms; only stricturing forms cause obstruction and only a few such patients require resection.

Angiodysplasia

Angiodysplasia is a vascular malformation that is a cause of haemorrhage from the colon, typically in patients over 60 years. The lesions are also called angiomas, haemangiomas and arteriovenous malformations. Angiodysplasias occur particularly in the ascending colon and caecum of elderly patients. The malformations consist of dilated tortuous submucosal veins and in severe cases the mucosa is replaced by massive dilated deformed vessels.

Clinical features

In the majority, the symptoms are subtle and patients can present with anaemia. About 10–15 per cent of patients have brisk bleeds, which may present as melaena or significant rectal bleeding. It is likely that in many patients in whom rectal bleeding has been attributed to diverticular disease, bleeding was in fact from angiodysplasia. There is an association with aortic stenosis (Heyde's syndrome).

Investigation

If the bleeding is not too brisk, colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. Capsule endoscopy is a relatively new technology that may detect small bowel lesions. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a 'blush' of contrast provided bleeding is above 1 mL/min. If this fails, a technetium-99m (99mTc)-labelled red cell scan may confirm and localise the source of haemorrhage.

Treatment

The first principle is to stabilise the patient. Following this, the

bleeding needs to be localised. Colonoscopy may allow cauterisation to be carried out. In severe uncontrolled bleeding, surgery becomes necessary. On-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (Figure 69.39). If it is still not clear exactly which segment of the colon is involved, then a subtotal colectomy may be necessary.

Ischaemic colitis

Ischaemia of the colon typically results from thrombosis or embolism. Sudden embolic events present with severe pain out of proportion to the degree of peritonism, bloody diarrhoea, severe haemodynamic instability and acidosis. Resuscitation and laparotomy are required with resection of gangrenous bowel and exteriorisation of the bowel. Mortality is extremely high. If the disease process is thrombotic in the context of global atherosclerosis, the presentation tends to be less dramatic with intermittent abdominal pain and rectal bleeding. Abdominal radiographs may show 'thumbprinting' and endoscopy may demonstrate haemorrhagic oedema. The left colon and, in particular, the splenic flexure are usually the worst affected. Angioplasty and bypass procedures can be performed in these circumstances, but are rarely required as symptoms usually settle spontaneously. In some cases, ulceration at the splenic flexure associated with ischaemic colitis may heal with stricturing and present with subsequent large bowel obstruction.

STOMAS

A colostomy (or ileostomy) stoma is an artificial opening made in the colon (or small intestine) to divert faeces and flatus outside the abdomen where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent (Summary box 69.18).

Figure 69.39 Angiodysplasia of the caecum demonstrated by transillumination with a colonoscope intraoperatively.

Summary box 69.18

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush
- Ileostomy effluent is usually liquid, whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- End-colostomy is usually sited in the left iliac fossa
- Whenever possible, patients should be counselled and sited by a stoma care nurse before operation

Loop colostomy

A transverse loop colostomy has in the past been used to defunction an anastomosis after an anterior resection. It is now less commonly employed, as it is difficult to manage and potentially disrupts the marginal arterial supply to the anastomosis. Loop transverse colostomies are also particularly prone to prolapse. A loop ileostomy is now more commonly used.

A loop left iliac fossa colostomy is still sometimes used to prevent faecal peritonitis developing following traumatic injury to the rectum, to facilitate the operative treatment of a high fistula in ano, for incontinence and to defunction a near obstructing rectal cancer prior to long course chemoradiotherapy (see Chapter 72).

A temporary loop colostomy is made by bringing a mobilised loop of colon to the surface, where it is held in place by a plastic bridge passed through a mesenteric window created just at the junction with the colon. Once the abdomen has been closed, the colostomy is opened, and the edges of the colonic incision are sutured to the adjacent skin margin (Figure 69.40). When firm adhesion of the colostomy to the abdominal wall has taken place, the bridge can be removed.

Following healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (proctogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, typically after the colostomy has been established for two months. Closure is usually possible with a circumstomal incision, which avoids a full laparotomy, but it is important for patient and surgeon to consider the risks of closure carefully as it does involve a bowel anastomosis. In some cases, a full laparotomy may be required for safe closure of the stoma.

End colostomy

This is formed after an abdominoperineal excision of the rectum or as part of a Hartmann's procedure bringing the divided colon

Figure 69.40 Temporary (loop) colostomy opened over a rod, and immediate suture of the colon wall to surrounding skin (alternatively, a skin bridge is used).

through a left iliac fossa trephine in rectus abdominis and skin. The colonic margin is then sutured to the adjoining skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the bony prominence of the anterosuperior iliac spine. The best site is usually through the lateral edge of the rectus sheath, above and medial to the bony prominence (Figure 69.41).

Closure of the lateral space between the intraperitoneal segment of the sigmoid colon and the peritoneum of the pelvic wall, to prevent internal herniation or strangulation of loops of small bowel through the deficiency, has been practised, but there is no good evidence that it is effective.

Loop ileostomy

A loop ileostomy is often used for defunctioning a low rectal anastomosis or an ileal pouch. A knuckle of ileum is pulled out through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled

Figure 69.41 A colostomy in the left iliac fossa.

Nils Kock, b. 1924 in Finland, Professor of Surgery, University of Goteborg, Sweden, pioneered the creation of an artificial reservoir within the abdomen from loops of small intestine in 1969.

over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near perfect defunction, but also the possibility of restoration of continuity by taking down the spout and reanastomosing the partially divided ileum.

The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be brought to the surface and the absence of odour. Care is needed when the ileostomy is closed, so that suture line obstruction does not occur. Closure of a loop ileostomy can be a technically challenging procedure, particularly if there are dense adhesions resulting from previous surgery.

End ileostomy

An end ileostomy is formed after a subtotal colectomy without anastomosis when it may later be reversed or may be permanent after a panproctocolectomy. The ileum is normally brought through the rectus abdominis muscle. Careful attention to the terminal ileal mesentery should be taken to ensure that it is not too bulky. The use of a spout was originally described by Bryan Brooke; this should project some 4 cm from the skin surface (Figure 69.42). A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

There may be an 'ileostomy flux' while the ileum adapts to the loss of the colon. While ileostomy output can amount to 4 or 5 litres per day, losses of 1–2 litres are more common. A consistent ileostomy output in excess of 1.5 litres is usually associated with dehydration and sodium depletion in the absence of intravenous therapy. The stools thicken in a few weeks and are semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care, and skin problems are unusual (Figure 69.43). Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and parastomal hernia.

Stoma bags and appliances

Stoma output is collected in disposable adhesive bags. Ileostomy appliances tend to be drainable bags, which are left in place for 48 hours, while colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. Many now incorporate an adhesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Figure 69.42 Ileostomy formation. Suturing the free extremity of the proximal ileum to the skin edges after eversion to form a spout (after Brooke).

Figure 69.43 Spouted ileostomy in the right iliac fossa.

Caecostomy

In unstable patients with advanced obstruction, a caecostomy may be useful. In late cases of obstruction, the caecum may become so distended and ischaemic that rupture of the caecal wall may be anticipated. This can occur spontaneously, giving rise to faecal peritonitis, or at operation, when an incision in the abdominal wall reduces its supportive role and allows the caecum to expand. In such a situation, it should be decompressed by suction as soon as the abdomen is opened. In thin patients, it may then be possible to carry out direct suture of the incised or perforated caecal wall to the abdominal skin of the right iliac fossa, although resection of this area is really the best treatment preferable. Following on-table lavage, via the appendix stump, the irrigating catheter can be left in place as a tube caecostomy.

Complications of stomas

Stoma complications are underestimated and common (Summary box 69.19). On occasion, these complications require surgical revision. Sometimes, this can be achieved with an incision immediately around the stoma, but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture of the parastomal hernia is associated with an almost 100 per cent risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary.

Summary box 69.19

Stoma complications

- Skin irritation
- Prolapse
- Retraction
- Ischaemia
- Stenosis
- Parastomal hernia
- Bleeding
- Fistulation

CONDITIONS CAUSING MALABSORPTION

Coeliac disease

Coeliac disease is the most common cause of malabsorption in the UK with a stated prevalence of 1:1800, although this may be an underestimate. It is characterised by a hypertrophic small bowel mucosa with atrophic villi and deep crypts. It is thought that loss of surface area and brush border enzymes results in malabsorption.

Coeliac disease is caused by gluten, a cereal protein although the exact mechanism remains unclear. There is a genetic component as the disease is more common in first-degree relatives and has an association with HLA B8. In children, coeliac disease presents with steatorrhoea and growth retardation. In adults, it results in diarrhoea, weight loss and anaemia.

The diagnosis is made after an endoscopic duodenal biopsy allows pathological examination of mucosa. The antiendomysial antibody tests have a very high sensitivity and specificity for coeliac disease, but many gastroenterologists would still want a biopsy to be entirely certain of the diagnosis.

Patients with coeliac disease have an increased risk of small bowel lymphoma and adenocarcinoma. Extraintestinal complications are dermatitis herpetiformis and neurological problems.

The key treatment for coeliac disease is withdrawal of gluten from the diet by avoiding wheat, rye and barley. Surgery is reserved for malignancy.

Bacterial overgrowth

The small intestine can become colonised with bacteria normally confined to the colon if there is stasis resulting in delayed bacterial clearance (blind loop syndrome, Figure 69.44). If this occurs in the upper intestine, the defect is chiefly of fat absorption; if in the lower intestine, there is vitamin B12 deficiency. There is relatively little effect on carbohydrate or protein metabolism.

Essentially, the stasis produces an abnormal bacterial flora, which prevents proper breakdown of fat and mops up the vitamins that are present. Sometimes, the only manifestation is anaemia, resulting from vitamin B12 deficiency but, if steatorrhoea occurs, other serious malabsorption features may follow including glossitis, osteomalacia, paraesthesia and peripheral neuropathy.

Improvement normally follows after intermittent therapy with oral antibiotics; metronidazole, ciprofloxacin and tetracycline are commonly used. Definitive treatment is surgical to remove the 'blind loop', but this is not always feasible.

FUNCTIONAL ABNORMALITIES

Constipation

There is no single definition of constipation; however, a bowel frequency of less than one every 3 days is commonly considered to be abnormal. Although constipation is often regarded as a trivial symptom, some patients are greatly disabled by abdominal pain, distension, reliance on laxatives and difficulty with defaecation. It is an extremely prevalent complaint in western

Figure 69.44 Common types of blind loop. (a) Self-filling: deficiency occurs; (b) self-emptying: no deficiency occurs; (c) long afferent loop stasis in Pólya gastrectomy; (d) jejunal diverticula; (e) intestinal stricture causing stasis; (f) 'stenosis-anastomosis loop' syndrome.

society. Some reports have put the annual prescription sales for laxatives in the UK at around £50 million. These are usually otherwise healthy individuals who seek help for constipation, but eat a normal diet and have a normal colon on endoscopy and barium enema. Constipation can be divided into:

- megacolon:
 - Hirschsprung's disease;
 - non-Hirschsprung's megacolon and megarectum;
- non-megacolon:
 - secondary to drugs or illness;
 - primary colonic problem.

Hirschsprung's disease

The nature and treatment of Hirschsprung's disease is discussed with other congenital disorders in Chapter 70.

Idiopathic megacolon and megarectum

This is a rare condition and the cause is not known, although in some it may result from poor toilet training during infancy and in others from a congenital abnormality of the intestinal myenteric plexus. In South America, Chagas disease is a common cause of megacolon resulting from infection with *Trypanosoma cruzi*. Volvulus and perforation can occur and treatment may require surgical resection.

Sir Frederick Treves, 1823–1953, surgeon, The London Hospital, attributed Hirschsprung's disease to congenital spasm of the distal segment, thus preceding the rediscovery of this concept by 50 years.

Clinical features

Idiopathic megacolon usually presents with severe constipation before the age of 20. Patients with idiopathic megarectum often present with faecal incontinence due to rectal faecal loading that requires manual evacuation. Patients with megacolon are more likely to present with abdominal distension and pain. On clinical examination, there may be a hard faecal mass arising out of the pelvis and, on rectal examination, there is a large faecal mass in the lumen. The anus is usually patulous, perianal soiling is common, and sigmoidoscopy is usually impossible but may show melanosis coli if the patient has been taking laxatives over many years.

Investigation

Anorectal physiology tests demonstrate delayed sensation and raised maximum tolerated volume. Full-thickness rectal biopsy shows normal ganglion cells, a finding that definitively distinguishes this condition from Hirschsprung's disease. Radiology studies will show gross faecal loading of the enlarged rectum and colon and an enlarged colon (Figure 69.45).

Medical treatment

This is directed at emptying the rectum and keeping it empty with enemas, washouts and occasionally, manual evacuation under anaesthesia. Thereafter, the patient is encouraged to develop a regular daily bowel habit, with the use of osmotic

laxatives to help the passage of semiformal stool. Rectal evacuation with suppositories and biofeedback therapy may be useful in resistant cases.

Surgical treatment

Surgical treatment is sometimes necessary if medical therapy fails. Options that are available include:

- resection of the dilated rectum and colon (Figure 69.46) back to normal-diameter colon followed by reconstruction with a coloanal anastomosis;
- colectomy with the formation of an ileorectal anastomosis if the rectum is spared;
- restorative proctocolectomy;
- vertical reduction rectoplasty, which is a procedure designed to reduce the volume of the rectum by at least 50 per cent;
- stoma formation, which may be used either as a salvage operation for failure of previous surgery or as a primary intervention.

Non-megacolon constipation

Drugs and a range of illnesses can result in constipation (see Summary boxes 69.20 and 69.21). Altering medication or addition of laxatives can be helpful for drug-related constipation, correction of underlying illness is clearly ideal where possible for the conditions in Summary box 69.21.

Summary box 69.20

Drugs that can cause constipation

- Benzodiazepines
- Carbamazepine
- Chlorpromazine
- Cholestyramine
- Iron
- Opiates, particularly codeine and morphine
- Tricyclic antidepressants
- Statins

Figure 69.46 Megacolon.

Summary box 69.21

Illnesses associated with constipation

- Neurological conditions
- Parkinson's disease
- Multiple sclerosis
- Diabetic nephropathy
- Spinal cord lesion
- Endocrine conditions
- Hypothyroidism
- Hypercalcaemia

There remain a group of patients with significant constipation who do not have any structural, pharmacological or other pathology to explain their symptoms. Some will have obstructed defaecation and this is discussed in Chapter 72. Others will have slow colonic transit, a disorder usually seen in women, which may have been present since childhood or may suddenly follow abdominal or pelvic surgery. Marker studies will reveal delayed transit, and the patient may or may not be able to empty the rectum normally.

Investigation

Whole-gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radio-opaque markers (Figure 69.47). Retention of more than 80 per cent of the shapes, 120 hours after ingestion, is abnormal.

Defaecating proctography will demonstrate intussusception and rectocele if they are causing obstructed defaecation (Chapter 72).

Treatment of slow colonic transit

- **Dietary fibre.** This is the first-line treatment for people with mild constipation. Constipation only resolves after several weeks of therapy and usually needs to be continued in the long term.
- **Laxatives.** It is important that patients do not fall into a cycle of laxative abuse. A number of types are available which include bulk, osmotic and stimulant agents.
- **Biofeedback.** This involves conditioning and coordination of the abdominal and pelvic compartments. It has been shown to be effective in those with a rectal evacuation problem and has also been used in slow transit with some benefit.
- **Surgery.** This is a difficult condition to treat medically; dietary measures are usually unsuccessful, and surgical treatment is justified after careful studies and when medical treatment has been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure, but the results are unpredictable. Studies show complications of intermittent small bowel obstruction (60 per cent), further surgery (30 per cent), constipation (25 per cent), diarrhoea (25 per cent) and incontinence (10 per cent). This may be explained in part by the argument that colectomy does not address the functional problem of the remaining bowel. Patients need to be carefully selected for surgery and psychological evaluation may be of benefit. Other types of surgery performed for slow transit constipation include stoma creation and segmental resection, but results are variable.

Figure 69.47 Whole-gut transit studied using radio-opaque markers. More than 80 per cent should have passed by day 5, demonstrating delayed transit here (courtesy of Dr D Nolan, John Radcliffe Hospital, Oxford, UK).

Irritable bowel syndrome

The term 'irritable bowel syndrome' (IBS) covers a range of symptom patterns that have a functional basis, i.e. no anatomical abnormality has been found. The clinical features are therefore variable but abdominal pain, bloating, irregularity of bowel habit and passage of mucous are common. Colonic investigations are typically performed to rule out organic disease (colonoscopy, barium enema or CT virtual colonoscopy).

Treatment is difficult by its nature. Many patients benefit from reassurance that there is no sinister pathology and symptomatic treatment; fibre or Fybogel for constipation, loperamide for diarrhoea. Reduction of caffeine intake and nicotine intake may be helpful. Antispasmodic agents are commonly prescribed, but the evidence base for this is poor. There is evidence of benefit for low-dose tricyclic antidepressants, but some patients are reluctant to use them because of a perceived stigma. Psychological treatments have been shown to be beneficial including hypnotherapy and cognitive behavioural therapy.

ENTEROCUTANEOUS FISTULA

An abnormal connection between small bowel and skin can occur in fistulating Crohn's disease or as a result of radiotherapy or abdominal trauma, but most commonly follows a surgical

complication – either a leak from an anastomosis or an inadvertent enterotomy during dissection. This can be very challenging to manage in patients with a high-output fistula (>500 mL/day). Low-output fistulae (<500 mL/day) can be expected to heal spontaneously, provided there is no distal obstruction. Reasons for failure of spontaneous healing also include:

- epithelial continuity between the gut and the skin;
- the presence of active disease where, for example, there is Crohn's disease or carcinoma at the site of the anastomosis or in the fistula track;
- an associated complex abscess.

The management of high output fistulae is based on well-established principles ('SNAP', see Summary box 69.22), as an early return to theatre to try and fix the problem in a septic, malnourished patient is doomed to failure.

Summary box 69.22

Principles of management of enterocutaneous fistulae (SNAP)

- **S**, elimination of Sepsis and skin protection
- **N**, Nutrition – a period of parenteral nutrition may well be required
- **A**, Anatomical assessment
- **P**, definitive Planned surgery

Infected collections are best identified at CT (Figure 69.48) and can be drained percutaneously. Skin protection is important, as small bowel effluent is caustic. Nutritional support must include fluid and electrolytes, which can be lost in high quantities from a proximal fistula as well as carbohydrates, protein, fat and vitamins. Judgements have to be made between enteral and parenteral feeding – enteral feeding has advantages but if the fis-

Figure 69.48 Computed tomography scan in a patient with a complex enterocutaneous fistula and an intra-abdominal abscess being drained with a CT-guided catheter.

tula is proximal or high output, total parenteral nutrition (TPN) will be required. Defining anatomy is best done after careful discussion with the radiologist – a sequence of contrast studies (follow-through, fistulogram and enema) may well be required to define bowel length and plan a surgical strategy. The surgery can on occasion be extremely technically demanding, and an anastomosis should not be fashioned in the presence of continuing intra-abdominal sepsis or when the patient is hypoproteinaemic.

LEARNING OBJECTIVES

To understand:

- The pathophysiology of dynamic and adynamic intestinal obstruction
- The cardinal features on history and examination
- The causes of small and large bowel obstruction
- The indications for surgery and other treatment options in bowel obstruction

CLASSIFICATION

Intestinal obstruction may be classified into two types:

- **Dynamic**, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (Figure 70.1 and Summary box 70.1).
- **Adynamic**, in which there is no mechanical obstruction; peristalsis is absent or inadequate (e.g. paralytic ileus or pseudo-obstruction).

Summary box 70.1

Causes of intestinal obstruction

Dynamic

- Intraluminal
 - Faecal impaction
 - Foreign bodies
 - Bezoars
 - Gallstones
- Intramural
 - Stricture
 - Malignancy
 - Intussusception
 - Volvulus
- Extramural
 - Bands/adhesions
 - Hernia

Adynamic

- Paralytic ileus
- Pseudo-obstruction

Figure 70.1 Pie chart showing the common causes of dynamic intestinal obstruction and their relative frequencies.

normal peristalsis and absorption until it becomes empty and collapses. Initially, proximal peristalsis is increased in an attempt to overcome the obstruction. If the obstruction is not relieved, the bowel continues to dilate, ultimately there is a reduction in peristaltic strength, resulting in flaccidity and paralysis.

The distension proximal to an obstruction is caused by two factors:

- **Gas:** there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90 per cent) and hydrogen sulphide.
- **Fluid:** this is made up of the various digestive juices (saliva 500 mL, bile 500 mL, pancreatic secretions 500 mL, gastric secretions 1 litre – all per 24 hours). This accumulates in the gut lumen as absorption by the obstructed gut is retarded. Dehydration and electrolyte loss are therefore due to:
 - reduced oral intake;

PATHOPHYSIOLOGY

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the bowel proximal to the obstruction dilates and the bowel below the obstruction exhibits

- defective intestinal absorption;
- losses as a result of vomiting;
- sequestration in the bowel lumen;
- transudation of fluid into the peritoneal cavity.

STRANGULATION

It is important to appreciate that the consequences of intestinal obstruction are not immediately life-threatening unless there is superimposed strangulation. When strangulation occurs, the blood supply is compromised and the bowel becomes ischaemic (Summary box 70.2).

Summary box 70.2

Causes of strangulation

- Direct pressure on the bowel wall
 - Hernial orifices
 - Adhesions/bands
- Interrupted mesenteric blood flow
 - Volvulus
 - Intussusception
- Increased intraluminal pressure
 - Closed-loop obstruction

Ischaemia from direct pressure on the bowel wall from a constricting band, such as a hernial orifice, is easy to understand.

Distention of the obstructed segment of bowel results in high pressure within the bowel wall. This can happen when only part of the bowel wall is obstructed as seen in Richter's hernias. Venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to impaired local perfusion and once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised, translocation and systemic exposure to anaerobic organisms and endotoxin occurs.

The morbidity and mortality associated with strangulation are largely dependent on the duration of the ischaemia and its extent. Elderly patients and those with comorbidities are more vulnerable to its effects. Although in strangulated external hernias the segment involved is often short, any length of ischaemic bowel can cause significant systemic effects secondary to sepsis and obstruction proximal to the obstruction can result in significant dehydration. When bowel involvement is extensive circulatory failure is common.

Closed-loop obstruction

This occurs when the bowel is obstructed at both the proximal and distal points (Figure 70.2). The distention is principally confined to the closed loop, distention proximal to the obstructed segment is not typically marked.

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the colon with a competent ileocaecal valve (present in up to one-third of individuals). This can occur with lesions as far distally as the rectum. The inability of the distended colon to decompress itself into the small bowel

Figure 70.2 Distention. Closed-loop obstruction with no proximal (A) or distal (C) distention and impending strangulation (B).

Figure 70.3 Carcinomatous stricture (X) of the hepatic flexure: closed-loop obstruction.

results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood flow in the wall. Unrelieved, this results in necrosis and perforation (Figure 70.3).

SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION

Internal hernia

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation (all are rare):

- the foramen of Winslow;
- a defect in the mesentery;
- a defect in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae – left paraduodenal and right duodenojejunal;

- caecal/appendiceal retroperitoneal fossae – superior, inferior and retrocaecal;
- intersigmoid fossa.

Internal herniation in the absence of adhesions is rare and a preoperative diagnosis is unusual. The standard treatment of an obstructed hernia is to release the constricting agent by division. This should not be undertaken in cases of herniation involving the foramen of Winslow, mesenteric defects and the paraduodenal/duodenojejunal fossae as major blood vessels run in the edge of the constriction ring. The distended loop in such circumstances must first be decompressed (minimising contamination) and then reduced.

Obstruction from enteric strictures

Small bowel strictures usually occur secondary to tuberculosis or Crohn's disease. Malignant strictures associated with lymphoma are uncommon, whereas carcinoma and sarcoma are rare. Presentation is usually subacute or chronic. Standard surgical management consists of resection and anastomosis. Resection is important to establish a histological diagnosis as this can be uncertain clinically. In Crohn's disease, strictureplasty may be considered in the presence of short multiple strictures without active sepsis.

Bolus obstruction

Bolus obstruction in the small bowel may be caused by gallstones, food, trichobezoar, phytobezoar, stercoliths and worms.

Gallstones

This type of obstruction tends to occur in the elderly secondary to erosion of a large gallstone directly through the gall bladder into the duodenum. Classically, there is impaction about 60 cm proximal to the ileocaecal valve. The patient may have recurrent attacks as the obstruction is frequently incomplete or relapsing as a result of a ball-valve effect. The characteristic radiological sign of gallstone ileus is Rigler's triad, comprising: small bowel obstruction, pneumobilia and an atypical mineral shadow on radiographs of the abdomen. The presence of two of these radiological signs has been considered pathognomic of gallstone ileus and is encountered in 40–50 per cent of the cases (note that pneumobilia is common following endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy). At laparotomy, the stone is milked proximally away from the site of impaction; it may be possible to crush the stone within the bowel lumen, if not, the intestine is opened at this point and the gallstone removed. If the gallstone is faceted, a careful check for other enteric stones should be made. The region of the gall bladder should not be explored.

Food

Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstone, with intraluminal crushing usually being successful.

Trychobezoars and phytobezoars

These are firm masses of undigested hair ball and fruit/vegetable fibre, respectively. The former is due to persistent hair chewing or sucking, and may be associated with an underlying psychiatric abnormality. Predisposition to phytobezoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum, otherwise open removal is required. A preoperative diagnosis is difficult even with high resolution computed tomography (CT) scanning.

Stercoliths

These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms

Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics (Figure 70.4). An attack may follow the initiation of antihelminthic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus, the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy, it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally, worms may cause a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as amebiasis.

Obstruction by adhesions and bands

Adhesions

In Western countries where abdominal operations are common, adhesions and bands are the most common cause of intestinal obstruction. The lifetime risk of requiring an admission to hospital for adhesional small bowel obstruction subsequent to abdominal surgery is around 4 per cent and the risk of requiring a laparotomy around 2 per cent. Adhesions start to form within

Figure 70.4 Obstruction of the small intestine due to *Ascaris lumbricoides* (courtesy of Asal Y Izzidien, Nenavah, Iraq).

Table 70.1 The common causes of intra-abdominal adhesions.

Infection	Peritonitis, tuberculosis
Chronic inflammatory conditions	Crohn's disease
Radiation enteritis	

hours of abdominal surgery. In the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in Table 70.1. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation (Summary box 70.3).

Summary box 70.3

Prevention of adhesions

Factors that may limit adhesion formation include:

- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots
- Minimising contact with gauze
- Covering anastomosis and raw peritoneal surfaces

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin and streptomycin, anticoagulants, antihistamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent or combination of agents has been convincingly shown to be effective. It is hoped that with the more widespread use of laparoscopic surgery, the incidence of intra-abdominal adhesions will reduce.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective, there are only two types – 'easy' flimsy ones and 'difficult' dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel and almost never involve the large bowel.

Bands

Usually only one band is culpable. This may be:

- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum, usually adherent to the parietes.

Acute intussusception

This occurs when one portion of the gut invaginates into an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between five and ten months of age. About 90 per cent of cases are idiopathic, but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer's patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy.

Children with intussusception associated with a pathological lead point such as Meckel's diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of two years, a pathological lead point is found in at least one-third of affected children. Adult cases are invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

Pathology

An intussusception is composed of three parts (Figure 70.5):

- the entering or inner tube (intussusceptum);
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

Intussusception may be anatomically defined according to the site and extent of invagination (Table 70.2). In most children, the intussusception is ileocolic (see Chapter 8, Figure 6.16). In adults, colocolic intussusception is more common (Summary box 70.4). The degree of ischaemia is dependent on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve. On CT scanning, the target sign may be evident and if present is pathognomonic. It is worth noting that rarely, intussusception has been noted on CT scanning in asymptomatic adults.

**Figure 70.5** Mechanism and nomenclature of intussusception.

Table 70.2 Types of intussusception in children (after RE Gross) ($n = 702$).

	Percentage of series
Ileoileal	5
Ileocolic	77
Ileoileocolic	12
Colocolic	2
Multiple	1
Retrograde	0.2
Others	2.8

Summary box 70.4

Intussusception

- Most common in children
- Adult cases are secondary to intestinal pathology, e.g. polyp, Meckel's diverticulum
- Ileocolic is the most common variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most paediatric cases
- Adults require surgery

Volvulus

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. The rotation causes obstruction to the lumen ($>180^\circ$ torsion) and if tight enough also causes vascular occlusion in the mesentery ($>360^\circ$ torsion). Bacterial fermentation adds to the distention and increasing intraluminal pressure impairs capillary perfusion. Mesenteric veins become obstructed as a result of the mechanical twisting and thrombosis results and contributes to the ischaemia.

Volvuli may be primary or secondary. The primary form occurs secondary to congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal volvulus and sigmoid volvulus. A secondary volvulus, which is the more common variety, is due to rotation of a segment of bowel around an acquired adhesion or stoma (Summary box 70.5).

Summary box 70.5

Volvulus

- May involve the small intestine, caecum or sigmoid colon; neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The most common spontaneous type in adults is sigmoid
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery is required to prevent or relieve ischaemia

Volvulus neonatorum

This occurs secondary to intestinal malrotation (see Chapter 8) and is potentially catastrophic.

Sigmoid volvulus

This is uncommon in Europe and the United States, but more common in Eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous Black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing causes are summarised in Figure 70.6. Other predisposing factors include a high residue diet and constipation. In Western populations, the condition is seen most often in elderly patients with chronic constipation; comorbidities are common and chronic psychotropic drug use is associated with this condition. Younger patients present earlier and the prognosis is inversely related to the duration of symptoms. Presentation can be classified as:

- **Fulminant:** sudden onset, severe pain, early vomiting, rapidly deteriorating clinical course;
- **Indolent:** insidious onset, slow progressive course, less pain, late vomiting.

Compound volvulus

This is a rare condition also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

Figure 70.6 Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.

CLINICAL FEATURES OF INTESTINAL OBSTRUCTION

Dynamic obstruction

The diagnosis of dynamic intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation. Obstruction may be classified clinically into two types:

- small bowel obstruction – high or low;
- large bowel obstruction (Summary box 70.6).

Summary box 70.6

Features of obstruction

- In **high small bowel obstruction**, vomiting occurs early, is profuse and causes rapid dehydration. Distension is minimal with little evidence of dilated small bowel loops on abdominal radiography
- In **low small bowel obstruction**, pain is predominant with central distension. Vomiting is delayed. Multiple dilated small bowel loops are seen on radiography
- In **large bowel obstruction**, distension is pronounced. Pain is less severe and vomiting and dehydration are later features. The colon proximal to the obstruction is distended on abdominal radiography. The small bowel will be dilated if the ileocaecal valve is incompetent

The nature of the presentation will also be influenced by whether the obstruction is:

- complete
- incomplete.

A complete small bowel obstruction has all the cardinal features (Summary box 70.7). In cases of complete large bowel obstruction, there is often a surprising lack of preceding symptoms. Both small and large bowel obstruction can present with more chronic symptoms in which the symptoms are intermittent or the obstruction is incomplete. Incomplete obstruction is also referred to as partial or subacute.

Summary box 70.7

Cardinal clinical features of acute obstruction

- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Presentation will be further influenced by whether the obstruction is:

- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is interference to blood flow.

The common causes of intestinal obstruction in Western countries and their relative frequencies are shown in Figure 70.1. The underlying mechanisms are shown in Summary box 70.2.

The clinical features vary according to:

- the location of the obstruction;
- the duration of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, the hernial orifices must be examined.

Pain

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and usually centred on the umbilicus (small bowel) or lower abdomen (large bowel). The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild and more constant diffuse pain. If there is no ischaemia and the obstruction persists over several days, pain reduces and can disappear.

The development of severe pain is suggestive of the presence of strangulation, especially if that severe pain is continuous. Beware the patient whose pain is not controlled with intravenous opiates. Colicky pain may not be a significant feature in postoperative simple mechanical obstruction and pain does not usually occur in paralytic ileus.

Vomiting

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses, the character of the vomitus alters from digested food to faeculent material, as a result of the presence of enteric bacterial overgrowth.

Distension

In the small bowel, the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (Figure 70.7). This can sometimes be provoked by 'flicking' the abdominal wall. Distension is a later feature in colonic obstruction.

Constipation

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The administration of enemas should be avoided in cases of suspected obstruction. This merely stimulates evacuation of bowel contents distal to the obstruction and confuses the clinical picture.

The rule that absolute constipation is present in intestinal obstruction does not apply in:

- Richter's hernia;
- gallstone ileus;
- mesenteric vascular occlusion;
- functional obstruction associated with pelvic abscess;
- all cases of partial obstruction (in which diarrhoea may occur).

Figure 70.7 Visible peristalsis. Intestinal obstruction due to a strangulated right femoral hernia, to which the arrow points.

Other manifestations

Dehydration

Dehydration is seen most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

Hypokalaemia

Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leukocytosis or leukopenia.

Pyrexia

Pyrexia in the presence of obstruction is rare and may indicate:

- the onset of ischaemia;
- intestinal perforation;
- inflammation or abscess associated with the obstructing disease.

Hypothermia indicates septicaemic shock or neglected cases of long duration.

Abdominal tenderness

Localised tenderness indicates impending or established ischaemia. The development of peritonism or peritonitis indicates impending or overt infarction and/or perforation. In cases of large bowel obstruction, it is important to elicit these findings in the right iliac fossa as the caecum is most vulnerable to ischaemia.

Bowel sounds

High-pitched bowel sounds are present in the vast majority of patients with intestinal obstruction. Normal bowel sounds are of negative predictive value. Bowel sounds may be scanty or absent if the obstruction is long-standing and the small bowel has become inactive.

Clinical features of strangulation

It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is almost entirely clinical; the clinical features are shown in Summary box 70.8.

Summary box 70.8

Clinical features of strangulation

- Constant pain, severe pain
- Tenderness with rigidity and peritonism
- Shock

In addition to the features above, it should be noted that:

- The presence of shock suggests underlying ischaemia especially if the shock is resistant to simple fluid resuscitation.
- In impending or established strangulation, pain is never completely absent.
- The presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.
- Generalised tenderness and the presence of rigidity indicate the need for early laparotomy.
- In cases of intestinal obstruction in which pain persists despite conservative management, even in the absence of the above signs, strangulation should be presumed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible and there is no expansile cough impulse. Skin changes with erythema or purplish discolouration are associated with underlying ischaemia (Figures 70.8 and 70.9).

Clinical features of intussusception

The classical presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale; between episodes he may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the 'redcurrant jelly' stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that hardens on palpation may be discerned but this is present in only 60 per cent of cases (Figure 70.10). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic

Figure 70.8 Skin discolouration over a strangulated incisional hernia.

Figure 70.9 Ischaemic small and large bowel in the strangulated incisional hernia.

intussusception, the apex may be palpable or even protrude from the anus.

Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

Differential diagnosis

Acute gastroenteritis

Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool,

Figure 70.10 The physical signs as recorded by Hamilton Bailey in a typical case of intussusception in an infant.

diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

Henoch–Schönlein purpura

Henoch–Schönlein purpura is associated with a characteristic rash and abdominal pain; intussusception may occur.

Rectal prolapse

This may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Clinical features of volvulus

Volvulus of the small intestine

This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in the West, it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus

This may occur as part of volvulus neonatorum or *de novo* and is usually a clockwise twist. It is more common in females in the fourth and fifth decades and usually presents acutely with the classic features of obstruction. Ischaemia is common. At first the obstruction may be partial, with the passage of flatus and faeces. In 25 per cent of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. The volvulus typically results in the caecum lying in the left upper quadrant. The diagnosis is not usually made preoperatively.

Sigmoid volvulus

The symptoms are of large bowel obstruction. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hic-cough and retching. Constipation is absolute. In the elderly, a more chronic form may be seen. In some patients, the grossly distended tortorted left colon is visible through the abdominal wall.

IMAGING

Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (Figure 70.11). An erect film may subsequently be requested when further doubt exists.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically (Summary box 70.9).

In intestinal obstruction, fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (Figure 70.12). These are most prominent on an erect film. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than one year old), a few fluid levels in the small bowel may be physiological. In this age group, it is difficult to distinguish large from small bowel in the presence of obstruction, because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

In patients without evidence of strangulation, there is a role for other imaging modalities. A recent systematic review and meta-analysis of the diagnostic and therapeutic role of 50–100 mL water-soluble contrast agent in adhesive small bowel obstruction included 14 prospective studies. The appearance of contrast in the colon 4–24 hours after administration had a sensitivity of 96 per cent and a specificity of 98 per cent in predicting resolution of small bowel obstruction. If contrast does not reach the colon, surgery is required in about 90 per cent of

Figure 70.11 Gas-filled small bowel loop; patient supine.

Summary box 70.9

Radiological features of obstruction (on plain x-ray)

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No/minimal gas is seen in the colon
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a 'concertina' or ladder effect
- Ileum – the distal ileum has been piquantly described by Wangenstein as featureless
- Caecum – a distended caecum is shown by a rounded gas shadow in the right iliac fossa
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another

patients. Administration of a water-soluble agent was also effective in reducing the need for surgery (OR 0.62; $p = 0.007$) and shortening hospital stay.

In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema should be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

Figure 70.12 Fluid levels with gas above; 'stepladder pattern'. Ileal obstruction by adhesions; patient erect.

The CT scan is now used very widely to investigate all forms of intestinal obstruction. It is highly accurate and its only limitations are in diagnosing ischaemia. It is important to remember that even with the best imaging techniques, the diagnosis of strangulation remains a clinical one.

Impacted foreign bodies may be seen on abdominal radiographs. It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds, whereas the latter can be confirmed radiologically. Fluid levels may also be seen in non-obstructing conditions such as gastroenteritis, acute pancreatitis and intra-abdominal sepsis.

Imaging in intussusception

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileocolic cases. A soft tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception (the claw sign) (Figure 70.13), but does not demonstrate small bowel intussusception. An abdominal ultrasound scan has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. CT scan is currently considered the most sensitive radiologic method to confirm intussusception, with a reported diagnostic accuracy of 58–100 per cent. The characteristic features of CT scan include a 'target' or 'sausage'-shaped soft-tissue mass with a layering effect, mesenteric vessels within the bowel lumen are also typical.

Imaging in volvulus

- In **caecal volvulus**, radiological abnormalities are identifiable in nearly all patients, but are often non-specific, with caecal dilatation (98–100 per cent), single air-fluid level (72–88 per cent), small bowel dilatation (42–55 per cent) and absence of gas in distal colon (82 per cent) reported as the most common abnormalities. A barium enema may be used

Figure 70.13 'Claw' sign of ileocolic intussusception. The barium in the intussusception is seen as a claw around a negative shadow of the intussusception (courtesy of RS Naik, Durg, India).

to confirm the diagnosis if there are no concerns about ischaemia, with an absence of barium in the caecum and a bird beak deformity. CT scanning is replacing barium enema as the imaging of choice in these less urgent cases.

- In **sigmoid volvulus**, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel, the two limbs are seen running diagonally across the abdomen from right to left, with two fluid levels seen, one within each loop of bowel (if an erect film is taken).
- In **volvulus neonatorum**, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

There are three main measures used to treat acute intestinal obstruction (Summary box 70.10).

Summary box 70.10

Treatment of acute intestinal obstruction

- Gastrointestinal drainage via a nasogastric tube
- Fluid and electrolyte replacement
- Relief of obstruction

Surgical treatment is necessary for most cases of intestinal obstruction but should be delayed until resuscitation is complete, provided there is no sign of strangulation or evidence of closed-loop obstruction

The first two steps are always necessary before attempting the surgical relief of obstruction and are the mainstay of postoperative management.

The three principles of surgical intervention are shown in Summary box 70.11.

Summary box 70.11

Principles of surgical intervention for obstruction

Management of:

- The segment at the site of obstruction
- The distended proximal bowel
- The underlying cause of obstruction

Supportive management

Nasogastric decompression is achieved by the passage of a non-vented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration, but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they are essential to reduce the risk of subsequent aspiration during induction of anaesthesia and post-extubation.

The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann's solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

Antibiotics are not mandatory but many clinicians initiate broad-spectrum antibiotics early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing surgery for intestinal obstruction.

Surgical treatment

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention (Summary box 70.12).

Summary box 70.12

Indications for early surgical intervention

- Obstructed external hernia
- Clinical features suspicious of intestinal strangulation
- Obstruction in a 'virgin' abdomen

The classic clinical advice that 'the sun should not both rise and set' on a case of unrelieved acute intestinal obstruction was based on the concern that intestinal ischaemia would develop while the patient was waiting for surgery. If there is complete obstruction, but no evidence of intestinal ischaemia, it is reasonable to defer surgery until the patient has been adequately resuscitated. Where obstruction is likely to be secondary to adhesions, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Assessment is directed to:

- the site of obstruction;
- the nature of the obstruction;
- the viability of the gut.

In cases of small bowel obstruction, the first manoeuvre is to deliver the distended small bowel into the wound. This permits access to the site of obstruction. The small bowel should be covered with moist swabs and the weight of the fluid-filled bowel supported such that the blood supply to the mesentery is not impaired.

Operative decompression should be performed whenever possible. This reduces pressure on the abdominal wound reducing pain and improving diaphragmatic movement. The simplest and safest method is to insert a large bore orogastric tube and to milk the small bowel contents in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced. It is important to ensure that the stomach is empty at the end of the procedure to prevent postoperative aspiration.

Rarely, decompression using Savage's decompressor within a seromuscular purse-string suture may be required. Its benefits should be balanced against the potential risk of septic complications from spillage and the risk of leakage from the suture line postoperatively. The type of surgical procedure

required will depend upon the cause of obstruction – division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (Table 70.3). Although frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 minutes with increased oxygenation and then reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Viability is also confirmed by colour, sheen and peristalsis. If at the end of this period, there is still uncertainty about gut viability, the gut should be resected if this does not result in short bowel syndrome. If the patient is septic such that they require inotropic therapy or would require postoperative level 3 intensive care treatment following resection, consideration should be given to raising both ends of the bowel as stomas. This is not only safe, but also allows regular assessment of the bowel.

Intestinal ischaemia/reperfusion injury has been described following reperfusion of ischaemic bowel with remote lung injury resulting from the release of inflammatory mediators. This should be borne in mind when dealing with ischaemic bowel. For example, if there is a volvulus with established infarction, detorsion should be avoided until the affected mesentery has been clamped and thus reperfusion injury prevented. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and can also be covered with omentum (Figures 70.14 and 70.15).

The surgical management of massive infarction is dependent on the patient's overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure to the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a policy of excision may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

Table 70.3 Differentiation between viable and non-viable intestine.

	Viable	Non-viable
Circulation	Dark colour becomes lighter Visible pulsation in mesenteric arteries	Dark colour remains No detectable pulsation
General appearance	Shiny	Dull and lustreless
Intestinal musculature	Firm Peristalsis may be observed	Flabby, thin and friable No peristalsis

Figure 70.14 Band adhesion causing closed-loop obstruction.

As laparoscopic surgery is now so common, it is important to note that small bowel obstruction and strangulation occur in relation to port site hernias. The risk of port site herniation is related to older age, higher body mass, trocar diameter and extension of the port site for tissue extraction. For laparoscopic cholecystectomy, the hernia rate is reported to be around 2 per cent. Obstruction and strangulation have even been reported through 5-mm port sites. Complications from these hernias may present in the early postoperative period and as a Richter's hernia. They can be easily overlooked and careful examination of port sites in patients with small bowel obstruction is essential.

Treatment of adhesions

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not usually be prolonged beyond 72 hours.

When laparotomy is required, although multiple adhesions may be found, only one may be causative. If there is absolute certainty that this is the cause of the obstruction, this should be divided and the remaining adhesions can be left *in situ* unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, the adhesions should be freed by sharp dissection from the duodeno-jejunal junction to the caecum. Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated with a seromuscular suture (Figure 70.15).

Figure 70.15 (a,b) Wall injury resulting from band compression, oversewn with an absorbable seromuscular suture.

Laparoscopic adhesiolysis may be considered in highly selected cases of small bowel obstruction (Summary box 70.13). This is classed as an advanced laparoscopic procedure and should only be undertaken by surgeons with advanced laparoscopic skills.

Summary box 70.13

Treatment of adhesive obstruction

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Repair serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis in the hands of advanced laparoscopic practitioners

Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble's plication operation;
- Charles–Phillips transmesenteric plication;
- intestinal intubation.

The latter three operations are now very rarely performed and can probably be consigned to the history books (they have never been required by the author).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. Mechanical obstruction is more likely if the patient has regained bowel function postoperatively which subsequently stops. Obstruction is usually incomplete and the majority settle with continued conservative management. Postoperative intra-abdominal sepsis is a potent cause of postoperative obstruction; CT scanning with oral contrast is of particular value in the assessment of the postoperative abdomen. A water-soluble contrast agent (50–100 mL) by mouth with a delayed plain abdominal x-ray is also of value (see p. 1189).

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema (see Chapter 8, Figure 6.17). Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70 per cent of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard, but is rare. Recurrent intussusception occurs in up to 10 per cent of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception toward its origin (Figure 70.16), making sure not to pull. The last part of the reduction is the most difficult (Figure 70.17). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common.

Figure 70.16 Diagram showing the method used to reduce an intussusception.

Figure 70.17 Reducing the terminal part of the intussusception (after RE Gross).

Intestinal malrotation with midgut volvulus, meconium ileus, Hirschsprung's disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in Chapter 8.

Intestinal atresia

Duodenal atresia and stenosis are the most common forms of intestinal obstruction in the newborn (see Chapter 8). Jejunal or ileal atresias are next in frequency, whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded.

There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall, through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so-called apple-peel atresia) (Figure 70.18), to multiple atresias ('string of sausages'). The obstructed proximal bowel is at risk of perforation, which may happen prenatally causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia, whereas abdominal distension is more prominent with

Figure 70.18 Apple-peel jejunal bowel atresia with obstructed proximal jejunum and collapsed distal ileum coiled round a remnant ileocolic artery (courtesy of MD Stringer, Leeds, UK).

ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

Surgery

Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

Meconium ileus

Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus, the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred *in utero*.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with mottling. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused microcolon. As the condition is caused by an autosomal recessive genetic defect, a family history may not be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels (>70 mmol/L).

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar gastrografin enema. This draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium

Figure 70.19 Bishop-Koop operation. This shows the completed procedure after grossly distended ileum has been resected. Because intestinal continuity is preserved, early closure of the ileostomy is not essential.

ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterotomy and irrigation of the bowel. The Bishop-Koop operation (Figure 70.19) with its irrigating stoma is now only rarely used.

TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION

Large bowel obstruction is usually caused by an underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or CT scan to confirm organic obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Care should be taken to ensure that the loss of tamponade of the abdominal wall does not lead to increased caecal distension and rupture (this starts with splitting along the line of the taenia coli on the antimesenteric border). Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. As surgery for malignant bowel cancer is technically challenging, wherever possible a suitably trained surgeon should perform the procedure. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. A primary anastomosis is safe if the patient's general condition is reasonable. If the lesion is irremovable (this is rarely the case), a proximal stoma (colostomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileo-descending colonic anastomosis.

For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications (Summary box 70.14).

Summary box 70.14

Management of left-sided large bowel obstruction

Contraindications to immediate resection include:

- Inexperienced surgeon
- Moribund patient
- Advanced disease

In rare instances, or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff, it is safest to bring the proximal colon to the surface as a colostomy. When possible, the distal bowel should be brought out at the same time (Paul-Mikulicz procedure) to facilitate subsequent closure. In the majority of cases, the distal bowel will not reach and is closed and returned to the abdomen (Hartmann's procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage.

Decompression of the obstructed left colon using endoscopically placed stents often as a bridge to surgery has been widely reported. However, as yet randomised trials have not shown improved outcomes compared to standard surgical treatment (Figure 70.20).

Treatment of caecal volvulus

At operation, the volvulus is usually found to be ischaemic and needs resection. If, viable, the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of fixation of the caecum to the right iliac fossa (caecopexy) and/or a

Figure 70.20 X-ray of stent inserted for malignant colonic obstruction.

caecostomy. Recurrence of volvulus after caecopexy has been reported in up to 40 per cent of cases.

Treatment of sigmoid volvulus

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. The tube should be secured in place with tape for 24 hours and a repeat x-ray taken to ensure that decompression has occurred. Successful deflation, as long as ischaemic bowel is excluded, will resolve the acute problem.

In young patients, an elective sigmoid colectomy is required. It is reasonable not to offer any further treatment following successful endoscopic decompression in the elderly as there is a high death rate (~80 per cent at two years) from causes other than recurrent volvulus. In elderly patients with comorbidities and recurrent episodes of volvulus, the options are resection or two point fixation with combined endoscopic/percutaneous tube insertion (gastrostomy tubes are frequently used for this purpose). Failure results in an early laparotomy, with untwisting of the loop and per anum decompression (Figure 70.21). When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved

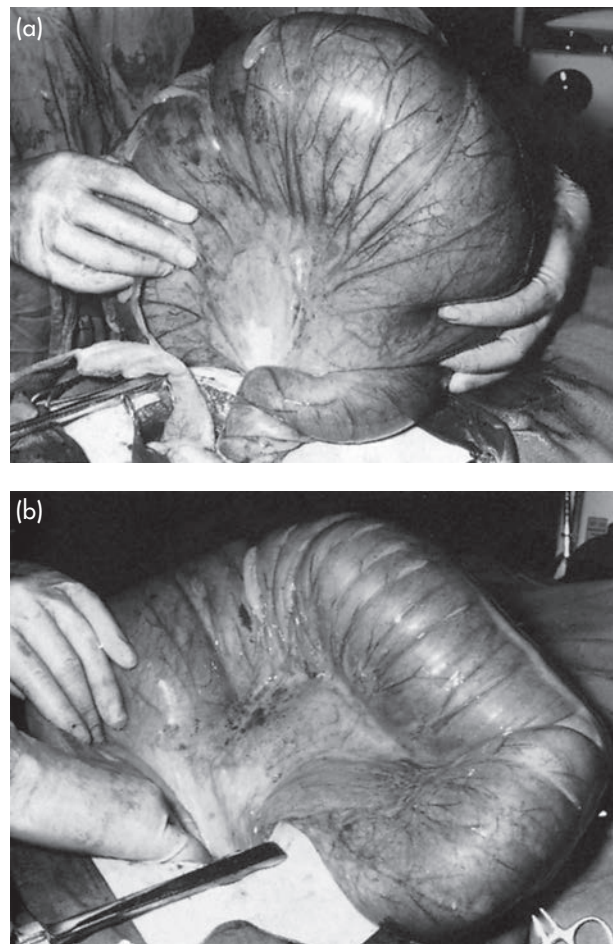

Figure 70.21 Volvulus of the sigmoid colon (a) before and (b) after untwisting (courtesy of SU Rahman, Manchester, UK).

Figure 70.22 The Paul-Mikulicz operation applied to volvulus of the pelvic colon.

safely. A Paul-Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (Figure 70.22); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann's procedure with subsequent reanastomosis can be carried out.

CHRONIC LARGE BOWEL OBSTRUCTION

The symptoms of chronic intestinal obstruction may arise from two sources – the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intraluminal (rare) – faecal impaction;
- intrinsic intramural – strictures (Crohn's disease, ischaemia, diverticular), anastomotic stenosis;
- extrinsic intramural (rare) – metastatic deposits (ovarian), endometriosis, stomal stenosis;

or functional:

- Hirschsprung's disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. In functional cases, the symptoms may have been present for months or years. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is less severe. Examination is unremarkable, save for confirmation of distension (which can be profound) (Figure 70.23) and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Investigation

Plain abdominal radiography confirms the presence of large bowel distension. All such cases should be investigated by a sub-

Figure 70.23 Gross functional distension.

Figure 70.24 Stomal stenosis causing large bowel obstruction.

sequent single-contrast water-soluble enema study, CT scan or endoscopic assessment to rule out functional disease (Summary box 70.15).

Summary box 70.15

Principles of investigation of possible large bowel obstruction

- In the presence of large bowel obstruction, a single contrast water-soluble enema or CT should be undertaken to exclude a functional cause

Organic disease requires decompression with either a laparotomy or stent. Stomal stenosis can usually be managed at the abdominal wall level (Figure 70.24). Surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

Functional disease requires colonoscopic decompression in the first instance and conservative management. Intestinal perforation can occur in patients with functional obstruction. Those at risk have such gross distension that the abdomen is rigid on palpation (Figure 70.23).

ADYNAMIC OBSTRUCTION

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure (i.e. in the myenteric (Auerbach's) and submucous (Meissner's) plexuses). The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised:

- **Postoperative.** A degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (see below).
- **Infection.** Intra-abdominal sepsis may give rise to localised or generalised ileus.
- **Reflex ileus.** This may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- **Metabolic.** Uraemia and hypokalaemia are the most common contributory factors.

Clinical features

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Colicky pain is not a feature. Distension increases pain from the abdominal wound. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels (if an erect film is felt necessary).

Management

Nasogastric tubes are not required routinely after elective intra-abdominal surgery. Paralytic ileus is managed with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular.

Specific treatment is directed towards the cause, but the following general principles apply:

- If a primary cause is identified, this must be treated.
- Gastrointestinal distension must be relieved by decompression.
- Close attention to fluid and electrolyte balance is essential.
- There is no place for the routine use of peristaltic

stimulants. Rarely, in resistant cases, medical therapy with a gastroprokinetic agent, such as domperidone or erythromycin may be used, provided that an intraperitoneal cause has been excluded.

- If paralytic ileus is prolonged, CT scanning is the most effective investigation; it will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any requirement for laparotomy. Otherwise the decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than 7 days or if bowel activity recommences following surgery and then stops again.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors (Summary box 70.16).

Summary box 70.16

Factors associated with pseudo-obstruction

- Metabolic
 - Diabetes
 - Hypokalaemia
 - Uraemia
 - Myxodema
 - Intermittent porphyria
- Severe trauma (especially to the lumbar spine and pelvis)
- Shock
 - Burns
 - Myocardial infarction
 - Stroke
 - Idiopathic
 - Septicaemia
 - Postoperative (for example, fractured neck of femur)
- Retroperitoneal irritation
 - Blood
 - Urine
 - Enzymes (pancreatitis)
 - Tumour
- Drugs
 - Tricyclic antidepressants
 - Phenothiazines
 - Laxatives
- Secondary gastrointestinal involvement
 - Scleroderma
 - Chagas' disease

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wrocław, Poland), described the myenteric plexus in 1862.

Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucous plexus of the alimentary tract in 1852.

Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of The Oswald Cruz Institute, and Professor of Tropical Medicine, The University of Rio de Janeiro, Brazil.

Sir William Heneage Ogilvie, 1887–1971, surgeon, Guy's Hospital, London, UK, reported his syndrome in 1948.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie's syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. Once confirmed, pseudo-obstruction requires treatment of any identifiable cause. If this is ineffective, intravenous neostigmine should be given (1 mg intravenously), with a further 1 mg given intravenously within a few minutes if the first dose is ineffective. During this procedure, it is best to sit the patient on a commode. ECG monitoring is required and atropine should be available. If neostigmine is not effective, colonoscopic decompression should be performed. Caecal perforation can occur in pseudo-obstruction. Abdominal examination should pay attention to tenderness and peritonism over the caecum and as with mechanical obstruction, caecal perforation is more likely if the caecal diameter is 14 cm or greater. Surgery is associated with high morbidity and mortality and should be reserved for those with impending perforation when other treatments have failed or perforation has occurred.

Rarely, an endoscopically placed tube colostomy is used as a vent for patients with those with a chronic unremitting condition.

LEARNING OBJECTIVES

To understand:

- The aetiology and surgical anatomy of acute appendicitis
- The clinical signs and differential diagnoses of appendicitis
- The investigation of suspected appendicitis
- Evolving concepts in management of acute appendicitis
- Basic surgical techniques, both open and laparoscopic
- The management of postoperative problems
- Less common conditions encountered

INTRODUCTION

The vermiform appendix is considered by most to be a vestigial organ; its importance in surgery results only from its propensity for inflammation, which results in the clinical syndrome known as 'acute appendicitis'. Acute appendicitis is the most common cause of an 'acute abdomen' in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed 'appendectomy' in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Advances in modern radiographic imaging have improved diagnostic accuracy, however the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science and as such it remains an enigmatic challenge and a reminder of the art of surgical diagnosis.

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of two years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Figure 71.1). In approximately one quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extra-peritoneal, lying behind the caecum or ascending colon. Rarely,

Figure 71.1 The various positions of the appendix (after Sir C Wakeley, London, formerly PRCS).

the caecum does not migrate during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gall bladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (Figure 71.2).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery or the terminal ileum and is itself subject to great variation. Sometimes, as much as the

Figure 71.2 Left-sided caecum and appendix due to intestinal malrotation (after Findley and Humphreys).

distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (Figure 71.3). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

Microscopic anatomy

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached upon by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (Figure 71.4). Crypts are present, but are not numerous. In the base of the crypts lie argentaffin cells

Figure 71.3 Mesoappendix displayed demonstrating the appendicular artery.

Figure 71.4 Normal vermiform appendix. The narrow lumen is bounded by mucosa which may be arranged in folds. There is usually abundant lymphoid tissue in the mucosa, especially in younger individuals. This may encroach on and further narrow the lumen. The mucosa is bounded by a relatively thin muscularis mucosa (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

(Kulchitsky cells), which may give rise to carcinoid tumours (see below under Carcinoid tumours). The appendix is the most frequent site for carcinoid tumours, which may present with appendicitis due to occlusion of the appendiceal lumen. The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune function results from appendectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see below under Aetiology).

ACUTE APPENDICITIS

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled 'Perforating inflammation of the vermiform appendix'. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that now bears his name.

The incidence of appendicitis seems to have risen greatly in the first half of the twentieth century, particularly in Europe, America and Australasia, with up to 16 per cent of the population undergoing appendectomy. In the past 30 years, the

Nicolai Kulchitsky, 1856–1925, Professor of Histology, Krakov, Ukraine, who left Russia after the revolution of 1917, and later worked at University College, London. He described these cells in 1897.

incidence has fallen dramatically in these countries, such that the individual lifetime risk of appendectomy is 8.6 and 6.7 per cent among males and females, respectively.

Acute appendicitis is relatively rare in infants, and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male–female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

Aetiology

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In developing countries that are adopting a more refined western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith or a stricture, is found in the majority of cases.

A faecolith (sometimes referred to as an ‘appendicolith’) is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris (Figure 71.5). Rarely, a foreign

body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic appendectomy or an interval appendicetomy in a patient treated conservatively (see below) (Figure 71.6). A fibrotic stricture of the appendix usually indicates previous appendicitis that resolved without surgical intervention (Figure 71.7). Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly *Oxyuris vermicularis* (pinworm), can proliferate in the appendix and occlude the lumen.

Pathology

Obstruction of the appendiceal lumen seems to be essential for the development of appendiceal gangrene and perforation. Yet, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in Northern Europe than at other times of the year.

Figure 71.5 Colonoscopic view of the lumen of the appendix showing intraluminal debris (courtesy of Professor D Winter, FRCSI, Dublin, Ireland).

Figure 71.6 Supine abdominal radiograph showing the presence of a large faecolith in the right iliac fossa (arrow).

Figure 71.7 Barium enema radiograph demonstrating faecaloliths of the appendix (arrow) with distal stricture of the appendix.

Lymphoid hyperplasia narrows the lumen of the appendix, leading to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (Figure 71.8). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination, and resulting in a phlegmonous mass or paracaecal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a ‘mucocoele’ of the appendix (Figure 71.9).

It is the potential for diffuse peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors that promote this process include

Figure 71.8 Acute appendicitis. A heavy acute inflammatory infiltrate extends through the full thickness of the wall of the appendix, destroying the mucosa, of which only a small island (M) remains, and the smooth muscle. The inflammation extends to involve the serosa (S) (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

Figure 71.9 Mucocoele of the appendix, following excision.

extremes of age, immunosuppression, diabetes mellitus and faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome (Summary box 71.1).

Summary box 71.1

Risk factors for perforation of the appendix

- Extremes of age
- Immunosuppression
- Diabetes mellitus
- Faecolith obstruction
- Pelvic appendix
- Previous abdominal surgery

Clinical diagnosis

History

The classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to midgut visceral

discomfort in response to appendiceal inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than, the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history (Summary box 71.2).

Summary box 71.2

Symptoms of appendicitis

- Periumbilical colic
- Pain shifting to the right iliac fossa
- Anorexia
- Nausea

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. Atypical presentations include pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may never produce somatic pain involving the anterior abdominal wall, but may instead cause suprapubic discomfort and tenderness. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80 or 90 is usual. However, in 20 per cent of patients, there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes, e.g. mesenteric adenitis (see below under Children).

Typically, two clinical syndromes of acute appendicitis can be discerned, **acute catarrhal (non-obstructive)** appendicitis and **acute obstructive** appendicitis, the latter characterised by a more acute course. The onset of symptoms is abrupt, and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so that the clinical picture may mimic acute intestinal obstruction.

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. In 1896, he was the first person to successfully suture a severed femoral artery; in 1898, he was the first person to do thoracoplasty for pulmonary tuberculosis and pioneered bone grafting techniques. William Mayo said of him 'the surgical genius of our generation'.

Signs

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa moving anticlockwise to the right iliac fossa will detect muscle guarding over the point of maximum tenderness, classically McBurney's point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness (Summary box 71.3).

Summary box 71.3

Clinical signs in appendicitis

- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing's sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value (Summary box 71.4).

Summary box 71.4

Signs to elicit in appendicitis

- Pointing sign
- Rovsing's sign
- Psoas sign
- Obturator sign

Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889, McBurney published a paper on appendicitis in which he stated 'I believe in every case the seat of greatest pain determined by the pressure of one finger has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus'.

Sir Vincent Zachary Cope, 1881–1975, surgeon, St Mary's Hospital, London, UK. He was a poet who wrote a poetry book under a pseudonym 'Zeta' describing the acute abdomen: 'The Acute Abdomen in Rhyme'. He described the differential diagnosis of acute appendicitis as:

Distension, rigidity, vomiting, pain,
Are actors abdominal which often deign
To act on behalf of the chest, spine or brain,
Or general ills of which typhoid's the main.

Thorkild Rovsing, 1862–1937, Professor of Surgery, Copenhagen, Denmark.

Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney's point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly because of the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with lax abdominal walls or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features, coupled with coincident medical

conditions, produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis. Delay in diagnosis, coupled with the technical difficulty of operating in the obese, makes it wiser to consider operating through a midline abdominal incision. Laparoscopy is particularly useful in the obese as it may obviate the need for a large abdominal incision.

Pregnancy

Appendicitis is the most common extrauterine acute abdominal condition in pregnancy, with a frequency of 1:1500–2000 pregnancies. Diagnosis is complicated by delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy. Fetal loss occurs in 3–5 per cent of cases, increasing to 20 per cent if perforation is found at operation.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (Table 71.1).

Children

The diseases most commonly mistaken for acute appendicitis are **acute gastroenteritis** and **mesenteric lymphadenitis**. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish **Meckel's diverticulitis** from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and **intussusception**. Appendicitis is uncommon before the age of two years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked,

Table 71.1 Differential diagnosis of acute appendicitis.

Children	Adult	Adult female	Elderly
Gastroenteritis	Regional enteritis	Mittelschmerz	Diverticulitis
Mesenteric adenitis	Ureteric colic	Pelvic inflammatory disease	Intestinal obstruction
Meckel's diverticulitis	Perforated peptic ulcer	Pyelonephritis	Colonic carcinoma
Intussusception	Torsion of testis	Ectopic pregnancy	Torsion appendix epiploicae
Henoch-Schönlein purpura	Pancreatitis	Torsion/rupture of ovarian cyst	Mesenteric infarction
Lobar pneumonia	Rectus sheath haematoma	Endometriosis	Leaking aortic aneurysm

and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

Adults

Terminal ileitis in its acute form may be indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn's disease or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. Renal ultrasound or intravenous urogram is diagnostic.

Right-sided acute pyelonephritis is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In perforated peptic ulcer, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule, there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium. An erect chest radiograph will show gas under the diaphragm in 70 per cent of patients. An abdominal computed tomography (CT) examination is valuable when there is diagnostic difficulty.

Testicular torsion in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis

and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

Adult female

It is in women of childbearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis, concentrating on menstrual cycle, vaginal discharge and possible pregnancy (see also Chapter 80). The most common diagnostic mimics are pelvic inflammatory disease (PID), Mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

Pelvic inflammatory disease

PID comprises a spectrum of diseases that include salpingitis, endometritis and tubo-ovarian sepsis. The incidence of these conditions is increasing and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adnexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained. Treatment is usually a combination of ofloxacin and metronidazole for 14 days. Transvaginal ultrasound can be particularly helpful in establishing the diagnosis. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

Mittelschmerz

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, a pregnancy test is negative, and symptoms usu-

ally subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

Torsion/haemorrhage of an ovarian cyst

This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation in women of childbearing years, untwisting of the involved adnexa and ovarian cystectomy should be performed, if necessary. Documented visualisation of the contralateral ovary is an essential medicolegal precaution prior to oophorectomy for any reason.

Ectopic pregnancy

It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion, or still more for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis, except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent, and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

Elderly

Diverticulitis

In some patients with a long sigmoid loop, the colon lies to the right of the midline, and it may be impossible to differentiate between diverticulitis and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for laparoscopy or exploratory laparotomy in the face of deterioration or lack of clinical response. Right-sided diverticulitis is unusual and may be clinically indistinguishable from appendicitis. Abdominal CT scanning is particularly useful in making the distinction. As with left-sided diverticulitis, treatment should be conservative with intravenous antibiotics with recourse to laparoscopy or laparotomy in the face of deterioration.

Intestinal obstruction

The diagnosis of intestinal obstruction is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated, with early resort to laparotomy.

Carcinoma of the caecum

When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (see

below under Carcinoid tumour) and an abdominal CT scan diagnostic.

Rare differential diagnoses

Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

Tabetic crises are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

Spinal conditions are sometimes associated with acute abdominal pain especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of **porphyria** and **diabetes mellitus** need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

Typhlitis or leukaemic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or **clostridial septicæmia** (especially *Clostridium septicum*) can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

Investigation

The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30 per cent of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (Table 71.2). A score of 7 or more is strongly predictive of acute appendicitis.

In patients with an equivocal score (5–6), abdominal ultrasound or contrast-enhanced CT examination further reduces the rate of negative appendectomy. Abdominal ultrasound examination is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90 per cent (Figure 71.10). Contrast-enhanced CT scan (Figure 71.11) is most useful in patients in whom there is diagnostic uncertainty, particularly older patients, in whom acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses. Selective use of CT scanning may be cost-effective by reducing both the negative appendectomy rate and the length of hospital stay (Summary box 71.5).

Treatment

The traditional treatment for acute appendicitis is appendectomy. While this remains standard teaching, there is an

 - Urea and electrolytes
 - Supine abdominal radiograph
 - Ultrasound of the abdomen/pelvis
 - Contrast-enhanced abdomen and pelvic computed tomography scan

emerging body of literature to support a trial of conservative management in those thought not to have obstructive appendicitis. Treatment is bowel rest and intravenous antibiotics, usually metranidazole and third-generation cephalosporin. The available data indicate successful outcomes in 80–90 per cent of patients, however there is an approximately 15 per cent recurrence rate within one year. This approach should be considered in patients with high operative risk (multiple comorbidities). As with conservative treatment of an appendix mass, patients over the age of 40 should be followed up to ensure there is no underlying malignancy (see below under Management of an appendix mass).

With regard to appendicectomy, there is a perception that emergency, often out of hours, operation is essential to prevent the increased morbidity and mortality of peritonitis. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. There is ample evidence that in the absence of purulent peritonitis, a single preoperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover Gram-negative bacilli, as well as anaerobic cocci, should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient's condition.

Appendicectomy

Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy in 1736. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait in May 1880. The patient recovered; however, the case was not reported until 1890. Meanwhile, Thomas Morton was the first to diagnose appendicitis, drain the abscess and remove the appendix with recovery, publishing his findings in 1887.

Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table. When a laparoscopic technique is to be used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (see below under Management of an appendix mass). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

Conventional appendicectomy

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called gridiron incision (*gridiron*: a frame of cross-beams to support a ship during repairs). The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney's point (Figure 71.12). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the midclavicular–midinguinal line (Figure 71.13). When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison's incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney's point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

Removal of the appendix

The caecum is identified by the presence of taenia coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane's forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (Figure 71.14a). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is crushed near its junction with the caecum in artery forceps, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the artery forceps and the ligature (Figure 71.14b). An absorbable 2/0 or 3/0 purse-string or 'Z' suture may then be inserted into the caecum about 1.25 cm from the base (Figure 71.14c). The stitch should pass through the muscle

Figure 71.14 (a) Mesoappendix divided between artery forceps and ligated. (b) Appendix crushed and ligated at its base and about to be divided. (c) 'Z' suture inserted prior to inversion of the appendiceal stump. (d) Appendiceal stump inverted, the 'Z' suture having been tied.

coat, picking up the taeniae coli. The stump of the appendix is invaginated (Figure 71.14d) while the purse-string or 'Z' suture is tied, thus burying the appendix stump. Many surgeons believe invagination of the appendiceal stump is unnecessary.

Methods to be adopted in special circumstances

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed, but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation should be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures.

Retrograde appendicectomy

When the appendix is retrocaecal and adherent, it is an advantage to divide the base between artery forceps. The appendiceal

vessels are then ligated, the stump ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

Laparoscopic appendicectomy

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of child-bearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. The operator stands to the patient's left and faces a video monitor placed at the patient's right foot (Figure 71.15). A moderate Trendelenburg tilt of the operating table assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. By elevating the appendix, the mesoappendix is displayed (Figure 71.16a). A dissecting forceps is used to create a window in the mesoappendix to allow the appendicular vessels to be coagulated or ligated using a clip applicator. The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (Figure 71.16b), divided (Figure 71.16c) and removed through one of the operating ports. It is not usual to invert the stump of the appendix (Figure 71.16d). A single absorbable suture is used to close the linea alba at the

Figure 71.15 Position of surgeon, assistants and equipment for laparoscopic appendectomy.

umbilicus, and the small skin incisions may be closed with subcuticular sutures.

Patients who undergo laparoscopic appendectomy are likely to have less postoperative pain and to be discharged from hospital and return to activities of daily living sooner than those who have undergone open appendectomy. While the incidence of postoperative wound infection is lower after the laparoscopic technique, the incidence of postoperative intra-abdominal sepsis may be higher in patients operated on for gangrenous or perforated appendicitis. There may be an advantage for laparoscopic over open appendectomy in obese patients and early pregnancy. At present, there seems little, if any, benefit from single incision laparoscopic surgery (SILS) for acute appendicitis.

Problems encountered during appendectomy

- **A normal appendix is found.** This demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix

Figure 71.16 Laparoscopic appendectomy. (a) Mesoappendix displayed; (b) ligation at the base of the appendix; (c) division of base; (d) appendectomy complete (courtesy of Professor O McAnena, FRCSI, Galway, Ireland).

is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

- **The appendix cannot be found.** The caecum should be mobilised, and the taenia coli should be traced to their confluence on the caecum before the diagnosis of 'absent appendix' is made.
- **An appendicular tumour is found.** Small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy (see below).
- **An appendix abscess is found and the appendix cannot be removed easily.** This eventuality is rare in the era of modern diagnostic imaging. Percutaneous drainage of the abscess and intravenous antibiotic treatment is to be preferred. If found at operation, the abscess should be drained and intravenous antibiotics administered. Very rarely in the face of a frankly necrotic appendix, a caecectomy or partial right hemicolectomy is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

Appendicitis complicating Crohn's disease

Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn's disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn's disease. In this situation, a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

Appendix abscess

Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for the insertion of a percutaneous drain. Rarely, this is unsuccessful and laparotomy through a midline incision is indicated.

Pelvic abscess

Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days after appendicitis; indeed, the patient may already have been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a boggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection (Figure 71.17). Pelvic ultrasound or CT scan will confirm. Traditionally, treatment has been through transrectal drainage under general anaesthetic, however increasing availability of radiologically guided percutaneous drainage has reduced the need considerably.

Figure 71.17 Sagittal computed tomography scan of pelvis showing pelvic abscess (white arrow). Note relationship with rectum (black arrow).

Management of an appendix mass

If an appendix mass is present and the condition of the patient is satisfactory, the standard treatment is the conservative Ochsner–Sherren regimen. This strategy is based on the premise that the inflammatory process is already localised and that inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons, it is wise to observe a non-operative programme but to be prepared to operate should clinical deterioration occur (Summary box 71.6).

Summary box 71.6

Criteria for stopping conservative treatment of an appendix mass

- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient's condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early

laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn's disease. Using this regimen, approximately 90 per cent of cases resolve without incident. The great majority of patients will not develop recurrence, and it is no longer considered necessary to remove the appendix after an interval of 6–8 weeks. Patients over the age of 40 should have colonoscopy and follow-up imaging to ensure resolution as a small minority (less than 5 per cent) may have an underlying appendicular or colonic malignancy.

Postoperative complications

Postoperative complications following appendectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications (Summary box 71.7).

Summary box 71.7

Checklist for unwell patient following appendectomy

- Examine the wound and abdomen for an abscess
- Consider a pelvic abscess and perform a rectal examination
- Examine the lungs – pneumonitis or collapse
- Examine the legs – consider venous thrombosis
- Examine the conjunctivae for an icteric tinge and the liver for enlargement, and enquire whether the patient has had rigors (pylephlebitis)
- Examine the urine for organisms (pyelonephritis)
- Suspect subphrenic abscess

Wound infection

Wound infection is the most common postoperative complication, occurring in 5–10 per cent of all patients. This usually presents with pain and erythema of the wound on the 4th or 5th postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of Gram-negative bacilli and anaerobic bacteria, predominantly *Bacteroides* species and anaerobic streptococci.

Intra-abdominal abscess

Approximately 8 per cent of patients following appendectomy will develop a postoperative intra-abdominal abscess. In an era of hospital discharge 24 to 48 hours following appendectomy, patients should be advised prior to discharge that a spiking fever, malaise and anorexia developing 5–7 days after operation is suggestive of an intraperitoneal collection and that urgent medical advice should be obtained. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage. Laparotomy should be considered in patients suspected of having intra-abdominal sepsis, but in whom imaging fails to show a collection, particularly those with continuing ileus.

Ileus

A period of adynamic ileus is to be expected after appendectomy, and this may last a number of days following removal of a

gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of continuing intra-abdominal sepsis and should prompt further investigation (see above). Rarely, early during postoperative recovery, a Richter's type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

Respiratory

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

Venous thrombosis and embolism

These conditions are rare after appendectomy, except in the elderly and in women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

Portal pyaemia (pylephlebitis)

This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by septicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate. A screen for underlying thrombophilia should be considered.

Faecal fistula

Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendectomy in Crohn's disease. Conservative management with low-residue enteral nutrition will usually result in closure.

Adhesive intestinal obstruction

This is the most common late complication of appendectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

Recurrent acute appendicitis

Appendicitis is notoriously recurrent. It is not uncommon for patients to attribute such attacks to 'biliousness' or dyspepsia. The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases shows fibrosis indicative of previous inflammation (Figure 71.18). Chronic appendicitis, per se, does not exist; however, there is evidence of altered neuroimmune function in the myenteric nerves of patients with so-called recurrent appendicitis (Büchler).

Neoplasms of the appendix

Carcinoid tumours

Carcinoid tumours (synonym: argentaffinoma) arise in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) and are most common in the vermiform appendix. Carcinoid tumour is found once in every 300–400 appendices subjected to histological examination and is ten times more common than any other neoplasm of the appendix. In many instances, the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it is frequently found in the distal third. The neoplasm feels moderately hard and, on sectioning the appendix, it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for chromogranin B (Figure 71.19). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases. Appendicectomy has been shown to be sufficient treatment, unless the caecal wall is involved, the tumour is 2 cm or more in size or involved lymph nodes are found, when right hemicolectomy is indicated.

Other appendiceal tumours

Goblet cell carcinoid tumour is an unusual variant, which exhibits a combination of endocrine and glandular differentiation. It has a more aggressive natural history and right hemicolectomy is indicated if the tumour is 2 cm or more in size, has greater than two mitoses per high power field, involved margins or lymphovascular invasion.

Primary adenocarcinoma of the appendix is extremely rare. It is usually of the colonic type and should be treated by right hemicolectomy (as a second-stage procedure if the condition is not recognised at the first operation).

Figure 71.18 Excised appendix showing the point of luminal obstruction with distal fibrosis.

Figure 71.19 Carcinoid tumour. A small incidental carcinoid tumour of the appendix. The tumour cells infiltrate the muscle arranged in small nests and trabeculae (arrows). Tumour cells are small and have inconspicuous nuclei. Inset: higher magnification of an immunohistochemical stain for chromogranin B shows a strong positive reaction (brown) of tumour cells (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

Mucinous cystadenoma

A mucin-secreting adenoma of the appendix may rupture into the peritoneal cavity (Figure 71.20), seeding it with mucus-secreting cells. Presentation is often delayed until the patient has gross abdominal distension as a result of pseudomyxoma peritonei, which may mimic ascites (Figure 71.21). Treatment consists of radical resection of all involved peritoneal surfaces and aggressive intraperitoneal chemotherapy (Sugarbaker). When diagnosed, patients should be referred to specialist centres that have the requisite facilities and experience to undertake the prolonged and complex surgery involved.

LEARNING OBJECTIVES

To understand:

- The anatomy of the rectum and its relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the rectum

To appreciate that:

- Carcinoma of the rectum is common and its symptoms are similar to those of benign disease and, hence, patients with such symptoms must be carefully evaluated

ANATOMY

Surgical anatomy

The rectum begins where the taenia coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum, and ends at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures: the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (Houston's valves) (Figure 72.1).

The adult rectum is approximately 12–18 cm in length and is conventionally divided into three equal parts: the upper third, which is mobile and has a peritoneal covering anteriorly and laterally; the middle third, where the peritoneum

covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis surrounded by fatty mesorectum and is separated from adjacent structures by fascial layers.

The lower third of the rectum is separated by a fascial condensation (Denonvilliers' fascia) from the prostate/vagina in front, and behind by another fascial layer (Waldeyer's fascia) from the coccyx and lower two sacral vertebrae (Table 72.1). These fascial layers are surgically important as they are a barrier to malignant invasion (Summary box 72.1).

Summary box 72.1**Anatomy of the rectum**

- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of superior, middle and inferior rectal vessels
- Although the lymphatic drainage follows the blood supply, the principal route is upwards along the superior rectal vessels to the para-aortic nodes

Blood supply

The **superior rectal artery** is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum. The arteries and their accompanying lymphatics lie within the loose fatty tissue of the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia).

The **middle rectal artery** arises on each side from the internal iliac artery (Figure 72.2) and passes to the rectum in the lateral ligaments. It is usually small (and often only present on one side) and breaks up into several terminal branches.

The **inferior rectal artery** arises on each side from the internal pudendal artery as it enters Alcock's canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischioanal fossa to enter the anal muscles (Figure 72.2).

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins: these unite to form the **superior rectal vein**, which later becomes the **inferior mesenteric vein**. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Figure 72.2 The rectum lying in the pelvis (coronal view). Note the curvatures corresponding to Houston's valves.

Lymphatic drainage

The lymphatics of the mucosal lining of the rectum communicate freely with those of the muscular layers. The usual drainage flow is upwards, and only to a limited extent laterally and downwards. For this reason, surgical clearance of malignant disease concentrates mainly on achieving wide resection of proximal lymph nodes. However, if the usual upwards routes are blocked (for example, by carcinoma), flow can reverse, and it is then possible to find metastatic lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE**Symptoms**

Rectal diseases are common and serious and can occur at any age. The symptoms of many of them overlap. In general, the inflammations affect younger age groups, while the tumours occur in the middle-aged and elderly. The common symptoms of rectal disease are shown in Summary box 72.2.

Summary box 72.2**Main symptoms of rectal disease**

- Bleeding per rectum
- Altered bowel habit
- Mucus discharge
- Tenesmus
- Prolapse

Bleeding

This is often bright red in colour but may be darker, and should be carefully investigated at any age.

Altered bowel habit

Early-morning stool frequency ('spurious diarrhoea') is a symptom of rectal carcinoma, while blood-stained frequent loose stools characterise the inflammatory diseases.

Discharge

Mucus and pus are associated with rectal pathology.

Tenesmus

Often described by the patient as 'I feel I want to go, but nothing happens', this is normally an ominous symptom of rectal cancer, but can occur with any rectal pathology.

Prolapse

This usually indicates either mucosal or full-thickness rectal wall descent.

Loss of weight

This usually indicates serious or advanced disease, e.g. hepatic metastases.

Signs

Because the rectum is accessible via the anus, these can be elicited by systematic examination. The patient is either positioned in the left lateral (Sims) position or examined in the knee-elbow position (Figure 72.3).

Inspection

Visual examination of the anus precedes rectal examination to exclude the presence of anal disease, e.g. fissure or fistula.

Digital examination

The index finger used with gentleness and precision remains a valuable test for rectal disease (Figure 72.4). Tumours in the lower and middle thirds of the rectum can be felt and assessed; by asking the patient to strain, even some tumours in the upper third can be 'tipped' with the finger. After it is removed, the finger should be examined for tell-tale traces of mucus, pus or blood. It is always useful to note the normal, as well as the abnormal findings on digital examination, e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids).

Proctoscopy

This procedure can be used to inspect the anus, anorectal junction and lower rectum (up to 10 cm) (Figure 72.5). Biopsy can be performed of any suspicious areas.

Figure 72.3 Positions for digital rectal examination. (a) Left lateral (Sims). (b) Knee-elbow. Redrawn with permission from Corman ML. *Colon and rectal surgery*, 3rd edn. London: JB Lippincott, 1992.

James Marion Sims, 1813–1883, gynaecological surgeon, the State Hospital for Women, New York, NY, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vaginovesical fistulae.

Charles Victor Mann, formerly surgeon, St Mark's Hospital and Royal London Hospital, London, UK.

Figure 72.4 Illustration showing how the various methods of examining the rectum reach different levels. Note that even cancers in the upper part of the rectum can be felt with the index finger, especially if the patient is asked to 'strain down' (courtesy of CV Mann).

Sigmoidoscopy

In the past, the sigmoidoscope was a rigid stainless steel instrument of variable diameter and normally 25 cm in length (Figure 72.5). This has in the main been replaced by a disposable plastic instrument. The rectum must be empty for proper inspection with a sigmoidoscope. Gentleness and skill are required for its use, and perforations can occur if care is not taken.

Flexible sigmoidoscopy

The 'flexiscope' can be used to supplement or replace rigid sigmoidoscopy (Figure 72.6). It requires skill and experience, and the lower bowel should be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon is within visual reach of this instrument (Summary box 72.3).

Summary box 72.3

Examination of the rectum

- Visual inspection of the perineum
- Digital examination
- Proctoscopy
- Sigmoidoscopy – rigid or flexible

INJURIES

The rectum or anal canal may be injured in a number of ways, all uncommon:

Figure 72.5 (a) A metal proctoscope and two different-sized metal Lloyd-Davies rigid sigmoidoscopes – small (diameter 20 mm). Since the advent of greater awareness of transmitted infection, disposable proctoscopes and sigmoidoscopes (b) have replaced the reusable metal types.

Figure 72.6 The flexible (60 cm) endoscope ('flexiscope').

- by falling in a sitting posture onto a pointed object: the upturned leg of a chair, handle of a broom, floor-mop, pitchfork or a broken shooting stick have all resulted in rectal impalement;
- by penetrating injury (including gunshots) to the buttocks;
- by sexual assault or sexual activity involving anal penetration;
- by the fetal head during childbirth, especially forceps-assisted.

Diagnosis

The anus should be inspected and the abdomen palpated. If rigidity or tenderness is present, early laparotomy or laparoscopy is indicated. A water-soluble contrast enema or computed tomography (CT) scan with rectal contrast is useful to identify perforation. Prior to the operation, a urethral catheter is passed, but if there is any possibility of urethral injury (suggested by difficulty passing urine, haematuria or high prostate on digital examination), a urethrogram should be performed first (see Chapters 76 and 78).

Treatment

If perforation is suspected, the rectum is examined under general anaesthetic with a finger and a sigmoidoscope, particular attention being directed to the anterior wall. If penetrating injury is confirmed, laparotomy or laparoscopy is then performed. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures. A defunctioning colostomy is usually required, constructed in the left iliac fossa. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. If the defect in the rectum is very large, resection may have to be contemplated, usually in the form of a Hartmann's procedure. Care must be taken to preserve sphincter function during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

FOREIGN BODIES IN THE RECTUM

The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Figure 72.7). A turnip has been delivered per anum by the use of obstetric forceps. A large soft rubber sex toy has been withdrawn by inserting a myomectomy screw into its lower end. A tumbler, mouth open downwards, has been extracted by filling the interior with a wet plaster of Paris bandage, leaving the end of the bandage protruding and allowing the plaster to set.

If insurmountable difficulty is experienced in grasping any foreign body in the rectum, a laparotomy is usually necessary, which allows the object to be pushed from above into the assistant's fingers in the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable (Summary box 72.4).

Figure 72.7 (a) Pepper pot in the rectum. On removal, it was found to be inscribed 'A present from Margate' (courtesy of Dr LS Carstairs, Royal Northern Hospital, London). (b) A screwdriver with a plastic handle (courtesy of Dr AK Sharma, Agra, India). (c) A live shell, which needed careful handling. (d) A large vibrator, which had pierced the lateral intraperitoneal rectal wall and caused peritonitis.

Summary box 72.4

Injuries to the rectum are serious and invariably require surgery

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

PROLAPSE

Mucosal prolapse

The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and thumb, it is evident that it is composed of no more than a double layer of mucous membrane (see below under Full-thickness prolapse) (Summary box 72.5).

Summary box 72.5**Rectal prolapse**

- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It commences as a rectal intussusception
- In children, the prolapse is usually mucosal and should be treated conservatively
- In the adult, the prolapse is often full thickness and is frequently associated with incontinence
- Surgery is necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

In infants

The direct downward course of the rectum, due to the as-yet undeveloped sacral curve (Figure 72.8), predisposes to this condition, as does the reduced resting anal tone, which offers diminished support to the mucosal lining of the anal canal.

In children

Mucosal prolapse often commences after an attack of diarrhoea, or from loss of weight and consequent loss of fat in the ischiorectal fossae. It may also be associated with cystic fibrosis, neurological causes and maldevelopment of the pelvis.

In adults

The condition in adults is often associated with third-degree haemorrhoids. In the female, a torn perineum, and in the male straining from urethral obstruction, predispose to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with weakness of the sphincter mechanism, but whether this is the cause of the problem or secondary to it is unknown.

Partial prolapse may follow an operation for fistula *in ano* where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Prolapsed mucous membrane is pink; prolapsed internal haemorrhoids are plum coloured and more pedunculated.

Treatment**In infants and young children**

- **Digital repositioning.** The parents are taught to replace the protrusion, and any underlying causes are addressed.

Figure 72.8 The absence of the normal sacral curve predisposes to rectal prolapse in an infant.

- **Submucosal injections.** If digital repositioning fails after 6 weeks' trial, injections of 5 per cent phenol in almond oil are carried out under general anaesthetic. As a result of the aseptic inflammation following these injections, the mucous membrane becomes tethered to the muscle coat.
- **Surgery.** Occasionally, surgery is required and, in such cases, the child is placed in the prone jack-knife position, the retrorectal space is entered, and the rectum is sutured to the sacrum.

In adults

- **Local treatments.** Submucosal injections of phenol in almond oil or the application of rubber bands are sometimes successful in cases of mucosal prolapse.
- **Excision of the prolapsed mucosa.** When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique can be used.

Full-thickness prolapse

Full-thickness prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor. The prolapse is thought to commence as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (Figure 72.9). On palpation between the finger and thumb, the prolapse feels much thicker than a mucosal prolapse, and obviously consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length contains anteriorly between its layers a pouch of peritoneum (Figure 72.10). When large, the peritoneal pouch may contain small intestine, which returns to the general peritoneal cavity with a characteristic gurgle when the prolapse is reduced. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children. In adults, it can occur at any age, but it is more common in the elderly. Women are affected six times more often than

Figure 72.9 Full-thickness rectal prolapse (courtesy of GD Adhia, Bombay, India).

Figure 72.10 Rectal prolapse containing a pouch of peritoneum.

men, and it is commonly associated with prolapse of the uterus. In approximately 50 per cent of adults, faecal incontinence is also a feature.

Differential diagnosis

In the case of a child with abdominal pain, prolapse of the rectum must be distinguished from **ileocaecal intussusception** protruding from the anus. Figures 72.11 and 72.12 make the differential diagnosis clear. In **rectosigmoid intussusception** in the adult, there is a deep groove (5 cm or more) between the emerging protruding mass and the margin of the anus, into which the finger can be placed.

Treatment

Surgery is required, and the operation can be performed via the perineal or the abdominal approaches. An abdominal rectopexy has a lower rate of recurrence but, when the patient is elderly and very frail, a perineal operation, sometimes performed under spinal anaesthetic, is usually safer. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach is often preferred in young men.

Perineal approach

These procedures have been used most commonly:

- **Thiersch operation.** This procedure, which aimed to place a steel wire or, more commonly, a silastic or nylon suture around the anal canal, has become obsolete. The reasons for

Figure 72.11 Partial prolapse of the rectum.

Figure 72.12 Intussusception protruding from the anus.

its lack of popularity were that the suture would often break or cause chronic perineal sepsis, or both, or the anal stenosis so created would produce severe functional problems.

- **Delorme's operation.** In this procedure, the rectal mucosa is removed circumferentially from the prolapsed rectum over its length (Figure 72.13). The underlying muscle is then plicated with a series of sutures, so that, when these are tied, the rectal muscle is concertinaed towards the anal canal. The anal canal mucosa is then sutured circumferentially to the rectal mucosa remaining at the tip of the prolapse. The prolapse is reduced, and a ring of muscle is created above the anal canal, which prevents recurrence.
- **Altemeier's procedure.** This consists of excision of the prolapsed rectum and associated sigmoid colon from below, and construction of a coloanal anastomosis.

Abdominal approach

The principle of all abdominal operations for rectal prolapse is to fix the rectum in its proper position. Many variations have been described, including inserting a sheet of polypropylene mesh between the rectum and the sacrum, hitching up the rectosigmoid junction with a Teflon sling to the front of the sacrum (Figure 72.14) or simply suturing the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so-called 'sutured rectopexy'. Recently, the technique has been performed laparoscopically, thus reducing the operative trauma and limiting the time in hospital.

As an abdominal rectopexy may lead to severe constipation, some surgeons recommend combining this procedure with resection of the sigmoid colon, so-called 'resection rectopexy'. Recently, an anterior mesh rectopexy has gained favour. In this procedure, a piece of mesh is fixed to the upper sacrum. The plane between the rectum and vagina is dissected, and the mesh placed into it and sutured to the rectum. This has the advantage of fixing the rectum in place anteriorly, where the prolapse starts, and reinforcing the rectovaginal septum which can bulge forward as a rectocele.

Figure 72.13 Delorme's operation for rectal prolapse. (a) The mucosa has been removed from the prolapse. (b) Interrupted sutures have been placed in the underlying muscle so that, when tied, the muscle is plicated. SOLITARY RECTAL ULCER

This is becoming a more commonly diagnosed problem. Classically, it takes the form of an ulcer on the anterior wall of the rectum. In this form, it can be mistaken for a rectal carcinoma or inflammatory bowel disease, particularly Crohn's disease. It may heal, leaving a polypoid appearance. Proctographic studies indicate that it is due to a combination of internal intussusception or anterior rectal wall prolapse and an increase in intrarectal pressure, usually caused by chronic straining as a result of constipation. The histological appearances confirm the diagnosis and are similar to the appearance of biopsies from a full-thickness overt rectal prolapse. The condition, although benign, is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by preventing the internal prolapse by biofeedback, an intrarectal stapling procedure or an abdominal rectopexy. In rare cases, rectal excision may be required.

PROCTITIS

Inflammation is sometimes limited to the rectum; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. The symptoms are tenesmus and the passage of blood and mucus and, in severe cases, of pus also. Although the patient has a frequent intense desire to defaecate, the amount of faeces passed at a time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, the mucosa feels swollen and is often tender. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish or exclude the diagnosis of specific infection by bacteriological examination and culture of the stools, examination of scrapings or swabs from ulcers and serological tests.

Non-specific proctitis is an inflammatory condition affecting the mucosa and, to a lesser extent, the submucosa, confined to

the distal rectum. In 10 per cent of cases, the condition extends to involve the whole colon (total ulcerative colitis) (Summary box 72.6).

Summary box 72.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel, but can spread to the proximal colon
- Causes bleeding, diarrhoea and tenesmus
- Treatment is usually conservative

Aetiology

This is unknown. The concept that the condition is a mild and limited form of ulcerative colitis (although actual ulceration is often not present) is the most acceptable hypothesis.

Clinical features

The patient is usually middle-aged and complains of slight loss of blood in the motions. Often, the complaint is one of diarrhoea but, on closer questioning, it transpires that usually one relatively normal action of the bowels occurs each day, although it is accompanied by some blood. During the day, the patient attempts to defaecate, with the passage of flatus and a little blood-stained faecal matter, which is interpreted as diarrhoea. On rectal examination, the mucosa feels warm and smooth. Often, there is some blood on the examining finger. Proctoscopic and sigmoidoscopic examination shows inflamed mucosa of the rectum, but usually no ulceration. The inflammation usually extends for only 5–15 cm from the anus, with the mucosa above this level being normal.

Treatment

The condition is usually self-limiting, but treatment with topical 5-aminosalicylic acid (5-ASA) compounds (Asacol, Pentasa) in the form of suppositories or foam enemas is usually effective. Topical steroids are a less effective alternative. In very severe resistant cases, oral steroids may have to be used to obtain remission. Rarely, surgical treatment is required as a last resort when the patient is desperate for relief of symptoms.

Ulcerative proctocolitis

Proctitis is present in a high percentage of cases of ulcerative colitis, and the degree of severity of the rectal involvement may influence the type of operative procedure (see Chapter 69).

Proctitis due to Crohn's disease

Crohn's disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic characteristics differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration and even a cobblestone appearance. Rectal Crohn's disease is often associated with severe perineal disease characterised by fistulation. Skip lesions are also often present in the rest of the colon or small bowel, or both.

Proctitis due to specific infections

Clostridium difficile

An acute form of proctocolitis caused by infection with *Clostridium difficile* can follow broad-spectrum antibiotic administration. A 'membrane' can sometimes be seen on proctoscopy ('pseudomembranous' colitis).

Bacillary dysentery

The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers. The examination of a swab taken from the ulcerated mucous membrane is more certainly diagnostic than stool microscopy.

Amoebic dysentery

The infection is more liable to be chronic, and exacerbations after a long period of freedom from symptoms often occur. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 69. Scrapings from the ulcer should be immersed in warm isotonic saline solution and sent to the laboratory for immediate microscopic examination.

Amoebic granuloma

This presents as a soft mass, usually in the rectosigmoid region. This lesion is frequently mistaken for a carcinoma. Sigmoidoscopy shows an ulcerated surface, but the mass is less friable than a carcinoma. A scraping should be taken, preferably with a small, sharp spoon on a long handle, and the material sent for immediate microscopic examination, as detailed above. A biopsy can also help. Treatment is as described in Chapter 69. Amoebic granuloma of the rectum is encountered from time to time in a patient who has never visited a country in which the disease is endemic.

Tuberculous proctitis

This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis, or tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis

Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but, later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

Lymphogranuloma venereum

The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from

the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although the enlargement may be subsiding by the time proctitis commences.

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV) may present with a particularly florid type of proctitis. In such patients, unusual organisms such as cytomegalovirus (CMV), herpes simplex virus and organisms such as *Cryptosporidium* are often found.

'Strawberry' lesion of the rectosigmoid

This results from an infection by *Spirochaeta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhoea, often scantily blood-stained. Occasionally, the diagnosis can be made by the demonstration of the specific organisms in the stools. More often, sigmoidoscopy is required. The characteristic lesion is thickened, somewhat raised mucosa with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pinpoints, giving the appearance of an over-ripe strawberry. A swab should be taken from the lesion and examined for Vincent's and fusiform organisms. Swabs from the gums and the throat are also advisable.

Rectal bilharziasis

Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the delta of the Nile.

In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; Chapter 76) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently present. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*.

Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae *in ano* are prone to develop.

Treatment

The primary treatment is systemic and should be undertaken by a specialist in tropical medicine. When the papillomas persist in spite of general treatment, they should be treated by local destruction.

Proctitis due to herbal enemas

This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a witch doctor, a virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with antibiotics, often prevent a fatal outcome if commenced early. Temporary colostomy is often advisable.

Treatment

General treatments should include bed rest in extreme cases. The stools should be kept soft. Suppositories of 5-ASA are often beneficial. Infective causes require specific treatment.

BENIGN TUMOURS

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of harbouring invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to give complete histological examination and exclude (or confirm) carcinoma, and also to prevent local recurrence. This is best done using endoscopic hot biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed, as further polyps are frequently found in the colon and treatment may be influenced. No rectal polyp should be removed until the possibility of a proximal carcinoma has been ruled out, otherwise local implantation of cancer cells may occur in the distally situated rectal wound.

The rectum shares substantially the same spectrum of polyps as the colon. Polyps are described chiefly in terms of their tissue organisation. Certain polyps that have features relevant to the rectum are now described.

Polyps relevant to the rectum

Villous adenomas

These have a characteristic frond-like appearance. They may be very large, and occasionally fill the entire rectum. These tumours have an enhanced tendency to become malignant – a change that can sometimes be detected by palpation with the finger; any hard area should be assumed to be malignant and should be biopsied. Rarely, the profuse mucous discharge from these tumours, which is rich in potassium, causes dangerous electrolyte and fluid losses (Figure 72.15).

Provided cancerous change has been excluded, these tumours can be removed by submucosal resection endoscopically, surgically *per anum* or by sleeve resection from above. Only very occasionally is rectal excision required. A technique known as transanal endoscopic microsurgery (TEM) has been developed, which has improved the endoanal approach for the local removal of villous adenomas. The method requires the insertion of a large operating sigmoidoscope. The rectum is distended by carbon dioxide insufflation, the operative field is magnified by a camera inserted via the sigmoidoscope, and the image is displayed on a monitor (Figure 72.16). The lesion is excised using specially designed instruments. The technique is highly specialised and takes a considerable amount of time to master.

Familial adenomatous polyposis

This autosomal dominantly inherited condition is characterised by the development of multiple rectal and colonic adenomas around puberty. It is due to mutation of the adenomatous polyposis coli (APC) gene, allowing genetic testing in the 75 per cent of families in which a mutation can be identified. A colonoscopy and biopsy will confirm the diagnosis. As this condition

Figure 72.15 Huge villous adenoma which occupied the lower half of the rectum and caused hypokalaemia.

is premalignant, a total colectomy must be performed; often, the rectum can be preserved, but regular flexible endoscopy and removal of polyps before they develop carcinoma are required. The operation of restorative proctocolectomy with ileal pouch–anal anastomosis is an alternative if proctectomy is required: the rectum is replaced by a ‘pouch’ of folded ileum (Chapter 69). A pan-proctocolectomy with permanent ileostomy is necessary in some instances, especially when patient follow up may be impractical.

Hyperplastic polyps

These are small, pinkish, sessile polyps, 2–4 mm in diameter and frequently multiple. They are common and generally harmless.

Inflammatory pseudopolyps

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty as the sigmoidoscopic appearances are usually associated with obvious signs of the inflammatory cause.

Juvenile polyp

This is a bright-red glistening pedunculated sphere (‘cherry tumour’), which is found in infants and children. Occasionally, it persists into adult life. It can cause bleeding, or pain if it prolapses during defaecation. It often separates itself, but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change, but should be treated if it is causing symptoms. It has a unique histological structure of large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (Figure 72.17). The rare autosomal dominantly inherited syndrome juvenile polyposis does confer an increased risk of gastrointestinal cancers. It is characterised by multiple juvenile polyps and a positive family history (Summary box 72.7).

Figure 72.16 (a–c) Transanal endoscopic microsurgery technique (see text).

Figure 72.17 Microscopic appearance of a juvenile polyp.

Summary box 72.7

Polyps in the rectum

- Are either single or multiple
- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid carcinomatous change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

Endometrioma

Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a very tender submucous elevation of the rectal wall. Endometrioma occurs usually between 20 and 40 years of age. Dysmenorrhoea and rectal bleeding (particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first line of therapy, but sometimes total abdominal hysterectomy and bilateral salpingo-oophorectomy and even bowel resection is required.

Haemangioma

Haemangioma of the rectum is an uncommon cause of serious haemorrhage. When localised in the lower part of the rectum or

anal canal, a haemangioma can be excised. When the lesion is diffuse, or lying in the upper part of the rectum, the symptoms simulate ulcerative colitis, and the diagnosis is often missed for a long period, or it is mistakenly thought to be a carcinoma. Selective angiography and embolisation may be helpful, but excision of the rectum is sometimes required.

Gastrointestinal stromal tumour

Smooth muscle tumours of the rectum are rare. If the mitotic rate is high, and if there is variation in nuclear number, size and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as malignant gastrointestinal stromal tumours (formerly leiomyosarcomas). The uncertainty in their behaviour means that treatment should, whenever possible, be by radical excision.

CARCINOMAS

Overall, colorectal cancer is the second most common malignancy in western countries, with approximately 18000 patients dying per annum in the UK. The rectum is the most frequent site involved.

Origin

It is now accepted that colorectal cancer arises from adenomas in a stepwise progression in which increasing dysplasia in the adenoma is due to an accumulation of genetic abnormalities (the adenoma–carcinoma sequence). In approximately 5 per cent of cases, there is more than one carcinoma present. Usually, these carcinomas present as an ulcer, but polypoid and infiltrating types are also common.

Types of carcinoma spread

Local spread

Local spread occurs circumferentially rather than in a longitudinal direction. After the muscular coat has been penetrated, the growth spreads into the surrounding mesorectum, but is initially limited by the mesorectal fascia. If penetration occurs anteriorly, the prostate, seminal vesicles or bladder become involved in the male; in the female, the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become involved, while posterior penetration may reach the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare.

Lymphatic spread

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction; below that level, the lymphatic spread is still upwards, but when the neoplasm lies within the field of the middle rectal artery, primary lateral spread along the lymphatics that accompany it is not infrequent.

Downward spread is exceptional, with drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelium lining the distal 1–2 cm of the anal canal.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs only late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery at a high level.

Atypical and widespread lymphatic permeation can occur in highly undifferentiated neoplasms.

Venous spread

The principal sites for blood-borne metastases are liver (34 per cent), lungs (22 per cent) and adrenals (11 per cent). The remaining 33 per cent are divided among the many other locations where secondary carcinomatous deposits tend to lodge, including the brain.

Peritoneal dissemination

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of progression

Dukes classified carcinoma of the rectum into three stages (Figure 72.18).

Dukes' staging

- **A**, The growth is limited to the rectal wall (15 per cent): prognosis excellent (90 per cent year survival).
- **B**, The growth is extended to the extrarectal tissues, but no metastasis to the regional lymph nodes (35 per cent): prognosis reasonable (70 per cent year survival).
- **C**, There are secondary deposits in the regional lymph nodes (50 per cent). These are subdivided into C1, in which the local pararectal lymph nodes alone are involved, and C2, in which the nodes accompanying the supplying blood vessels are implicated up to the point of division. This does not take into account cases that have metastasised beyond the regional lymph nodes or by way of the venous system: prognosis is poor (40 per cent year survival).

A stage D is often included, which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic.

Figure 72.18 The three cardinal stages of progression of the neoplasm (after C Dukes, FRCS).

Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, but the tumour–node–metastasis (TNM) classification is now recognised internationally as the optimum classification for staging.

TNM staging

T represents the extent of local spread and there are four grades:

- T1 tumour invasion through the muscularis mucosae, but not into the muscularis propria;
- T2 tumour invasion into, but not through the muscularis propria;
- T3 tumour invasion through the muscularis propria, but not through the serosa (on surfaces covered by peritoneum) or mesorectal fascia;
- T4 tumour invasion through the serosa or mesorectal fascia.

N describes nodal involvement:

- N0 no lymph node involvement;
- N1 between one and three involved lymph nodes;
- N2 four or more involved lymph nodes.

M indicates the presence of distant metastases:

- M0 no distant metastases;
- M1 distant metastases.

The prefix ‘p’ indicates that the staging is based on histopathological analysis, and ‘y’ that it is the stage after neoadjuvant treatment, which may have resulted in downstaging.

Histological grading

In the great majority of cases, carcinoma of the rectum is a columnar-celled adenocarcinoma. The more nearly the tumour cells approach normal shape and arrangement, the less aggressive the tumour is. Conversely, the greater the percentage of cells of an undifferentiated type, the more aggressive the tumour is:

- Low grade, well-differentiated 11 per cent prognosis good;
- Average grade, 64 per cent prognosis fair;
- High grade, undifferentiated tumours 25 per cent prognosis poor.

Vascular and perineural invasion are poor prognostic features, as is the presence of an infiltrating (rather than pushing) margin and tumour budding. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Primary mucoid carcinoma gives rise to a rapidly growing bulky growth that metastasises very early and the prognosis of which is very poor (Summary box 72.8).

Clinical features

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for six months or more (Summary box 72.9), and the diagnosis is often delayed in younger patients as these symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential to prevent this.

Summary box 72.8

Pathology and staging of rectal cancer

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important as this profoundly affects surgical treatment
- Although lymphatic spread follows the blood supply of the rectum, most occurs in an upwards direction via the superior rectal vessels to the para-aortic nodes
- The TNM classification is the internationally recognised staging system

Summary box 72.9

Early symptoms of rectal cancer

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

Bleeding

Bleeding is the earliest and most common symptom. There is nothing characteristic about the time at which it occurs, nor is the colour or the amount of blood distinctive; often, the bleeding is slight in amount and occurs at the end of defaecation, or is noticed because it has stained underclothing. Indeed, more often than not, the bleeding in every respect simulates that of internal haemorrhoids (haemorrhoids and carcinoma sometimes coexist).

Sense of incomplete defaecation

The patient’s bowels open, but there is the sensation that there are more faeces to be passed (**tenesmus**, a distressing straining to empty the bowels without resultant evacuation). This is a very important early symptom and is almost invariably present in tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus (‘bloody slime’).

Alteration in bowel habit

This is the next most frequent symptom. The patient may find it necessary to start taking an aperient or to supplement the usual dose. A patient who has to get up early in order to defaecate, or one who passes blood and mucus in addition to faeces (‘early-morning bloody diarrhoea’), is usually found to be suffering from carcinoma of the rectum. Often, it is the patient with an annular carcinoma at the rectosigmoid junction who suffers with increasing constipation, and the one with a growth in the ampulla of the rectum who has early-morning diarrhoea.

Pain

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, and is caused

by some degree of intestinal obstruction. When a deep carcinomatous ulcer of the rectum erodes the prostate or bladder, there may be severe pain. Pain in the back, or sciatica, occurs when the cancer invades the sacral plexus.

Weight loss is suggestive of hepatic metastases.

Investigation

Abdominal examination

Abdominal examination is normal in early cases. Occasionally, when an advanced annular tumour is situated at the rectosigmoid junction, signs of obstruction of the large intestine are present. By the time the patient seeks advice, metastases in the liver may be palpable. When the peritoneum has become studded with secondary deposits, ascites usually results.

Rectal examination

In many cases, the neoplasm can be felt digitally: in early cases as a nodule with an indurated base. When the centre ulcerates, a shallow depression will be found, the edges of which are raised and everted. On bimanual examination, it may be possible to feel the lower extremity of a carcinoma situated in the rectosigmoid junction. After the finger has been withdrawn, if it has been in direct contact with a carcinoma, it is smeared with blood or mucopurulent material tinged with blood. When a carcinomatous ulcer is situated in the lower third of the rectum, involved lymph nodes can sometimes be felt as one or more hard, oval swellings in the mesorectum posteriorly or posterolaterally above the tumour. In females, a vaginal examination should be performed and, when the neoplasm is situated on the anterior wall of the rectum, with one finger in the vagina and another in the rectum, very accurate palpation can be carried out.

Proctosigmoidoscopy

Proctosigmoidoscopy will always show a carcinoma, if present, provided that the rectum is emptied of faeces beforehand.

Biopsy

Using biopsy forceps (Figure 72.19) via a sigmoidoscope, a portion of the edge of the tumour can be removed. If possible, another specimen from the more central part of the growth should also be obtained.

Colonoscopy

A colonoscopy is required if possible in all patients to exclude a synchronous tumour, be it an adenoma or a carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy will need changing. If a full colonoscopy is not possible, a CT colonography or barium enema can be performed.

Figure 72.19 Yeoman's biopsy forceps.

When a stenosing carcinoma is present, it may not be possible using these investigations, especially colonoscopy, to visualise the proximal colon. However, in view of the high incidence of synchronous tumours, it is imperative that a colonoscopy is always performed either before or within a few months of surgical resection.

Differential diagnosis

When an adenoma shows evidence of induration or unusual friability, it is almost certain that malignancy has occurred, even in spite of biopsy findings to the contrary. On the other hand, biopsy is invaluable in distinguishing carcinoma from an inflammatory stricture or an amoebic granuloma. The possibility of a neoplasm being an endometrioma should always be considered in patients with dysmenorrhoea. The possibility of a carcinoid tumour in atypical cases must be remembered. In the last four instances, biopsy should establish the correct diagnosis. The solitary ulcer syndrome has already been mentioned above (Summary box 72.10).

Summary box 72.10

Diagnosis and assessment of rectal cancer

All patients with suspected rectal cancer should undergo:

- Digital rectal examination
- Sigmoidoscopy and biopsy
- Colonoscopy if possible (or CT colonography or barium enema)

All patients with proven rectal cancer require staging by:

- Imaging of the liver and chest, preferably by CT
- Local pelvic imaging by magnetic resonance imaging and/or endoluminal ultrasound

Treatment

Some form of excision of the tumour remains the mainstay of treatment, if at all possible, because of the extreme suffering entailed if the neoplasm remains. However, the management of rectal cancer has become increasingly complex, because of the various surgical, neoadjuvant and adjuvant options available, and is best delivered in a multidisciplinary setting. Before treatment can be planned, it is necessary to assess:

- the fitness of the patient;
- the extent of spread of the tumour.

Assessment of spread should include CT of the chest and abdomen to exclude distant metastases (Figure 72.20). Ultrasonography of the liver and a chest radiograph are decreasingly used alternatives. Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal.

Endoluminal ultrasound, performed using a probe placed in the rectal lumen, can be used to assess the local spread of the tumour (Figure 72.21), and is particularly accurate in staging the degree of penetration through the rectal wall in early tumours. CT is not particularly accurate in local staging, which is usually performed using magnetic resonance imaging (MRI), which allows assessment of the circumferential resection margin and adjacent structures (Figure 72.22).

Figure 72.20 Computed tomography scan of the liver in a patient with a rectal cancer showing multiple liver metastases.

Figure 72.21 Endoluminal ultrasound. The probe is in the rectal lumen and shows a rectal tumour invading through the rectal wall.

Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim in most cases. Even in the presence of widespread metastases, a rectal excision should be considered, as this is often the best means of palliation. The presence of liver metastases does not necessarily rule out the feasibility of cure: the results of surgery for liver metastases have greatly improved, with long-term survival being achieved in over a third of patients.

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the administration of a course of neoadjuvant (preoperative) chemoradiotherapy over approximately 6 weeks may reduce its size and make curative surgery

Figure 72.22 Magnetic resonance imaging scan of pelvis showing extensive T3 rectal carcinoma invading the left side of the mesorectum.

possible. The administration of preoperative 'short-course' (5 days) neoadjuvant radiotherapy in resectable rectal cancer cases significantly reduces the incidence of local recurrence, but at the cost of some increase in complication rates.

For patients who are unfit for radical surgery, who have very early tumours or who have widespread metastases, a local procedure such as transanal excision, laser destruction or interstitial radiation should be considered.

When a rectal excision is possible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter whenever feasible. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is ≥ 2 cm above the anal canal. Although removal of the rectum and anus with a permanent colostomy (abdominoperineal excision) was often required for tumours of the lower third of the rectum in the past, the introduction of the stapling gun has enabled many more of these patients to be treated by a sphincter-saving procedure. The principles of the operation involve radical excision of the neoplasm, removal of the mesorectum that surrounds it and high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the rectum has been adequately mobilised, it is removed, and the rectal stump is washed out. Restoration of continuity by direct end-to-end anastomosis (manually or by stapling) must be carried out by a meticulous technique to reduce the risks of anastomotic breakdown.

Rectosigmoid tumours and those in the upper third of the rectum are removed by 'high anterior resection', in which the rectum and mesorectum are taken to a margin 5 cm distal to the tumour, and a colorectal anastomosis is performed. This does not usually require defunctioning. The retention of at least a part of the rectum results in good postoperative function.

For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. total mesorectal excision (TME). A temporary protecting stoma is usually formed after TME (see below under Anterior resection).

Preoperative preparation

Traditionally, the bowel was prepared by mechanical cleansing using a combination of diet, purgatives and enemas (e.g. senna,

Picolax). This approach is now used more selectively, with many surgeons reserving full bowel preparation for those undergoing a low anterior resection, and clearing only the distal bowel using enemas in the rest. Prophylactic systemic antibiotics are given preoperatively. The antibiotic regimen must be active against both aerobic and anaerobic organisms. At present, a suitable prescription would be cefuroxime 750 mg plus metronidazole 500 mg given on induction of anaesthesia. If a patient comes to surgery with a loaded colon, on-table intraoperative irrigation can be performed.

All patients should see a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence.

Blood and electrolyte deficiencies are corrected. Before commencing the operation, an indwelling catheter is inserted into the bladder (Summary box 72.11).

Summary box 72.11

Preoperative preparation

- Counselling and siting of stomas
- Correction of anaemia and electrolyte disturbance
- Cross-matching of blood
- Bowel preparation
- Deep vein thrombosis prophylaxis
- Prophylactic antibiotics
- Insertion of urinary catheter

Local operations

For small, low-grade T1 tumours, local removal should be curative in the vast majority; only a small percentage of these will have involved lymph nodes which are left undetected and unremoved by this approach. For these tumours, especially in the unfit or in patients who will not accept a colostomy, local removal has been used. This is usually done via the anus and the TEM technique is often used.

There is considerable controversy, however, as to whether such local techniques should be used for potentially curable lesions as they do not allow full histopathological staging or deal with the mesorectal or lymphatic spread of the tumour. Certainly the local recurrence rate (mostly due to lymph node metastases within the mesorectum) after local excision of T2 tumours is in the region of 20 per cent, which is unacceptable in all but those in whom radical surgery is associated with very high risk. Combined local excision with chemotherapy and radiotherapy has been suggested as a curative treatment for T1 and T2 tumours, but is not widely accepted.

Anterior resection

In the last 30 years, there has been a move to extend sphincter-saving operations to treat most tumours of the middle third of the rectum, and indeed many in the lower third. Over the last five years it has become clear that this surgery can be performed laparoscopically with at least equivalent oncological outcomes. This is, however, technically challenging and should only be performed in this way by adequately trained and experienced surgeons.

Following a midline incision, the liver and the peritoneum are examined for metastases. The sigmoid and descending colon are freed by dividing the peritoneal reflection on the left side and mobilised to the midline on their mesentery. The splenic flexure is dissected and the left ureter and testicular or ovarian vessels are identified. The mesocolon is divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery (Figure 72.23) is ligated and divided. Most surgeons divide the descending colon at this point.

The rectosigmoid mesentery is separated from the sacrum by sharp dissection with scissors or, more usually, diathermy. Great care is exercised to ensure that the hypogastric nerves are identified and preserved. It is essential that, as the distal dissection proceeds, the surgeon remains outside the mesorectal fascia and stays within the bloodless 'holy' plane outside it. The peritoneal incision is carried anteriorly around the rectum, and the seminal vesicles or the vaginal wall are identified so that Denonvilliers' fascia behind them is cleared by a dissection leading down to the prostate or vagina. The condensations of fascia that attach the rectum to the pelvic side walls and are known as the lateral ligaments are dissected by diathermy. This tissue contains the middle rectal vessels, which sometimes require separate ligation and division.

The rectum is mobilised to the pelvic floor, and a right-angled clamp is placed at least 1 cm below the tumour. The rectum can then be stapled transversely. After the rectum and sigmoid colon have been excised, continuity is re-established by the method depicted in Figure 72.24. Although a single loop of colon is often used for the anastomosis, a short J-shaped colonic pouch may be

Figure 72.23 Exposure and division of the inferior mesenteric vessels flush with the aorta (high tie) in the course of an abdominoperineal excision of the rectum. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

Figure 72.24 Low anterior resection by the double stapling method. The rectum has been excised, and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling gun is used to construct (a) a straight low coloanal anastomosis or (b) a colonic pouch–anus anastomosis.

constructed with the aim of increasing neorectal capacity and thus reducing postoperative bowel frequency and urgency. Many surgeons believe that such a temporary defunctioning stoma is required for all colorectal and coloanal anastomoses that are constructed below the peritoneal reflection.

Occasionally, although the rectum, together with its tumour, can be removed adequately, continuity cannot be restored by a stapling technique. In such cases, it may still be possible to restore continuity by bringing the colon down to the anal canal and constructing a sutured coloanal anastomosis via the transanal route (Figure 72.25).

It is important to ensure that any free tumour cells released by mobilisation of the rectum are destroyed by irrigation of the rectal lumen with a cancericidal solution such as 1 per cent cetrimide. By so doing, the implantation of such cells and subsequent local recurrence is prevented. However, it should be realised that, although a small percentage of local recurrences are due to implantation of shed cells, the majority result from inadequate removal of the tumour at the time of the initial operation. It is now known that micrometastases are present in the mesorectum, and these are the most likely cause of local recurrence after rectal excision. It is essential to remove all the mesorectum during anterior resection or abdominoperineal

Figure 72.25 Abdominotransanal–coloanal anastomosis. (a) The rectum has been excised, and the mucosa from the distal anorectal stump has been removed, leaving the rectal muscle intact. The proximal colon has been brought down through the rectal muscular cuff to be anastomosed to the anal mucosa via the transanal route. (b) The completed coloanal anastomosis. A covering ileostomy has been performed to allow the anastomosis to heal.

excision, the procedure known as TME. TME is now being practised worldwide and appears to reduce the risks of local recurrence substantially (Figure 72.26). This has been largely due to the work of Heald, who has shown that training in the technique improves local recurrence rates, and has been central to its widespread adoption. However, it is unlikely that surgery alone will deal adequately with all the micrometastases in the pelvis. Consequently, neoadjuvant radiotherapy may have added benefit (see below under Radiotherapy).

Hartmann's operation

This is an excellent procedure in an old and frail patient in whom there is concern about anal sphincter function or the viability of an anastomosis. Through an abdominal incision, the rectum is excised, the anorectal stump is transected, usually with a stapler and an end colostomy is formed.

Abdominoperineal excision of the rectum

This operation is still required for some tumours of the lower third of the rectum, which are unsuitable for a sphincter-saving procedure. A large catheter is passed to allow easy identification of the urethra. Traditionally, the procedure was performed by two surgeons operating simultaneously, one via the abdomen and the other via the perineum with the patient in the Trendelenburg lithotomy position. More recently, there has been a shift to completing the abdominal procedure first (with the patient in the Lloyd-Davies position, in which the legs are in supports set lower than the lithotomy position), and then placing the patient prone and completing the operation via the

perineum from behind (cylindrical or extra-levator abdominoperineal excision). There is evidence that this allows a wider dissection at the level of the pelvic floor, increasing complete resection rates and reducing local recurrence, although increasing morbidity.

The abdominal procedure is carried out laparoscopically or via a midline laparotomy, and is performed in the same way as an anterior resection, except that dissection stops before the pelvic floor is reached (at the level of the seminal vesicles in men or the cervix in women), to avoid 'coning down' onto the tumour at the level of the pelvic floor. The end colostomy is formed and the wounds closed.

The site for the colostomy in the left iliac fossa should have been marked preoperatively by the stoma care nurse in consultation with the patient. If this has not been possible, it should be sited equidistant from the umbilicus and the left anterior superior iliac spine at the linea semilunaris.

The perineal procedure is then carried out via an elliptical incision between the tip of the coccyx and the central perineal point around the anus. This is deepened until the pelvic floor is reached. This is divided as far laterally as possible, to maximise clearance of the tumour, which will be lying at this level (Figure 72.27). The dissection is extended posteriorly by incising Waldeyer's fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Some surgeons routinely remove the coccyx to improve access and surgical margins. The dissection is deepened until the mobilisation performed via the abdomen is reached posteriorly and laterally. The plane between the rectum and the prostate in the male or between the rectum and the vagina in the female is developed, with particular care to avoid the membranous urethra in the male. The catheter within it should be palpated so that it can be avoided. The posterior wall of the vagina can be excised with the rectum if an advanced anterior tumour is present. The whole of the anus and rectum is drawn downwards and removed through the perineal wound.

Figure 72.26 Plane of dissection for total mesorectal excision.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Richard John (Bill) Heald, consultant colorectal surgeon, Basingstoke, UK.

Care of the colostomy

This is much the same as care of an ileostomy (Chapter 69). Within a very short time, the colostomy acts once or twice a day. Many patients are now taught to empty their lower colon by irrigation through the colostomy: this has many advantages for the patient who requires an inactive colostomy while at work.

Endoluminal stenting

An increasingly used alternative is placement of an endoluminal stent, which can be done endoscopically, often with fluoroscopic guidance. This can either be used as a palliative procedure, or to relieve obstruction and permit elective rather than emergency surgery to be undertaken. Only colonic and upper rectal tumours are suitable for stenting.

Palliative colostomy

This is indicated only in cases giving rise to intestinal obstruction, or where there is gross infiltration of the neoplasm. It is sometimes possible to resect the tumour later (e.g. after chemoradiotherapy) and, in some cases, cure, rather than palliation, is achieved.

Figure 72.27 (a, b) Separation and division of the pubococcygeus and puborectalis muscles in the course of the perineal phase of an abdominoperineal excision of the rectum. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

Other palliative procedures

Occasionally, a neodymium:yttrium–aluminium–garnet (Nd:YAG) laser can be used to deal with an obstructing or bleeding lesion, and intraluminal debulking has also been described.

More extensive operations

When the carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures. Thus, in the male, in whom spread is usually to the bladder, a cystectomy and resection of the rectum can be performed. In the female, the uterus acts as a barrier, usually preventing spread from the rectum to the bladder. Accordingly, a hysterectomy should be undertaken in addition to excision of the rectum. Pelvic evisceration for carcinoma of the rectum is justifiable only when the surgeon is confident that the growth can be completely removed.

Pelvic exenteration (Brunschiwig's operation)

The aim is to remove all the pelvic organs, together with the internal iliac and the obturator groups of lymph nodes (Figure 72.28). Ligation of both internal iliac arteries diminishes the blood loss. A rectus abdominis flap can be used to fill the empty pelvis. Special care must therefore be taken to suture the perineal skin accurately, and to avoid pressure necrosis of the perineal incision by nursing the patient on alternate sides. Some form of urinary diversion is necessary, usually an ileal conduit.

Liver resection

Single or several well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided the patients are carefully selected, a reasonable long-term

Figure 72.28 Radical pelvic exenteration, indicating the extent of the dissection and the viscera removed. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

survival rate can be achieved (approximately 40 per cent in some series). Such surgery is usually carried out in a specialised liver unit, and it is generally advised that it takes place after the primary lesion has been dealt with (Summary box 72.12).

Summary box 72.12

Surgery for rectal cancer

- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal excision with total mesorectal excision
- Most cases can be treated by anterior resection with the colorectal anastomosis being achieved with a circular stapling gun
- A smaller group of low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Preoperative radiotherapy can reduce local recurrence
- Adjuvant chemotherapy can improve survival in node-positive disease
- Liver resection in carefully selected patients offers the best chance of cure for single or well-localised liver metastases

Radiotherapy

Various trials have been performed to investigate the effect of adjuvant radiotherapy given either pre- or postoperatively. The overall results suggest that, provided an adequate dose is given, neoadjuvant radiotherapy can reduce the incidence of local recurrence; however, long-term survival is not affected. Recent studies have combined radiotherapy with chemotherapy in an attempt to shrink an extensive tumour prior to surgical excision. In some cases using this combined therapy, the results can be spectacular, and it has become the standard initial treatment for locally advanced tumours, allowing potentially curative resection in cases that would otherwise be inoperable. Indeed, in a few cases, the tumour appears to respond completely, making the approach to further management controversial.

Palliative irradiation can be given for inoperable primary tumours or local recurrence, especially when painful. Papillon refined a technique of intracavity radiation that applies the treatment direct to the tumour from the rectal lumen. In a selected series of early cases, the results were good (five-year survival rates of more than 70 per cent).

Chemotherapy

A variety of drugs has been tried both as an adjuvant therapy and for the treatment of disseminated disease. The most frequently used drug is 5-fluorouracil (5-FU) or its oral equivalent capecitabine. There is now good evidence that systemic 5-FU alone or in combination with oxaliplatin can improve survival by 10–15 per cent in node-positive disease. Similarly, studies in which 5-FU has been infused into the portal vein during and immediately after the primary operation have shown a small benefit. Such intraportal adjuvant therapy is thought to kill malignant cells, which are released into the circulation during operative manipulation of the tumour, and thus prevent the formation of metastases. Recently, some exciting new drugs have become available, the most notable being irinotecan and cetuximab. Both agents have been shown to have a moderate but beneficial effect in disseminated disease, but it remains to be seen whether they will be effective in an adjuvant setting.

Results of surgery for rectal cancer

In specialised centres, the resectability rate may be as high as 95 per cent, with an operative mortality of less than 5 per cent. Overall, the five-year survival rate is about 50 per cent.

Survival rates are influenced by TNM/Dukes' stage, with node-positive patients doing worse than those with node-negative lesions (Figure 72.29). The bowel cancer screening programmes being introduced in many countries will result in earlier stage at presentation, and consequently improved outcome. The lower the tumour is in the rectum, the worse the outlook. Histological grade also influences outcome, with undifferentiated lesions having the worse prognosis.

Local recurrence

Local recurrence after rectal excision is a major problem. The patient often presents with persistent pelvic pain, which radiates down the legs if the sacral roots are involved. Bladder symptoms may occur. If recurrence develops after abdominoperineal excision, a swelling or induration may be present in the perineum, or an abscess or discharging sinus may develop. After sphincter-saving resection, there may be a change in bowel habit or the passage of blood per rectum. Sigmoidoscopic examination may reveal friable tissue at the anastomosis which, when biopsied, confirms the diagnosis. However, the recurrence is usually situated extrarectally, and is detected either as induration on digital examination or by endoluminal ultrasonography, CT or MRI. These investigations can also detect recurrence before it causes symptoms. Local recurrence rates vary between 2 and 25 per cent and are higher after abdominoperineal excision than after sphincter-saving resection. The most common cause is inadequate removal of the whole tumour at the initial operation. This is due to the presence of microscopic tumour deposits in

Figure 72.29 Cancer-specific survival rates following surgery for rectal cancer according to Dukes' stages. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

the mesorectum. If the mesorectum is removed in its entirety, the local recurrence rate can be reduced to less than 5 per cent.

Less common causes of local recurrence include implantation of viable cells on the suture line and the development of a new primary tumour. Eighty per cent of all local recurrences develop within two years following surgery, and they are very difficult to treat. The best prospect of salvage is by surgical resection. However, it is possible to achieve apparently complete removal in only a minority of cases, and will usually involve hysterectomy, bladder resection and even partial sacrectomy. Radiotherapy also has an important role, but many patients will have already been exposed to a maximal dose during the treatment of the primary tumour.

Carcinoid tumour

Carcinoid tumour originates in the submucosa, with the mucous membrane over it being intact. Consequently, it seldom produces evidence of its presence in the early stages, when it presents as a small plaque-like elevation. The incidence of clinical malignancy, i.e. the occurrence of metastases, is 10 per cent.

This is much less than that for carcinoid tumour of the small intestine, but it is greater than that for carcinoid tumour of the appendix. Multiple primary carcinoid tumours of the rectum are not infrequent. The neoplasm is of slow progression, and usually metastasises late. Large carcinoids (over 2 cm) are almost always malignant.

Treatment

Local excision is sufficient treatment for small carcinoids. Resection of the rectum is advisable if the growth is more than 2.5 cm in diameter, if recurrence follows local excision or if the growth is fixed to the perirectal tissues. Even when metastases are present, resection may prolong life.

CHAPTER 73

The anus and anal canal

LEARNING OBJECTIVES

To understand:

- The anatomy of the anus and anal canal and their relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the anus and anal canal
- That anal disease is common and its treatment tends to be conservative, although surgery may be required
- That too aggressive or inappropriate surgery may render the patient permanently disabled

ANATOMY AND PHYSIOLOGY

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge – the anorectal ‘bundle’ or ‘ring’.

Anal canal anatomy

The anorectal ring

The anorectal ring marks the junction between the rectum and the anal canal (Figure 73.1). It is formed by the joining of the puborectalis muscle (Figure 73.2), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects.

The puborectalis muscle

Puborectalis, part of the funnel-shaped muscular pelvic diaphragm, maintains the angle between the anal canal and rectum and hence is an important component in the continence mechanism (Figure 73.2). The muscle derives its nerve supply from the sacral somatic nerves, and is functionally indistinct from the external anal sphincter. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling. It gives off fibres that contribute to the longitudinal muscle layer.

The external sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided into

Figure 73.1 Relevant anatomy of the anus. Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.

deep, superficial and subcutaneous portions, it is a single muscle (Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of its fibres are attached posteriorly to the coccyx, whereas anteriorly they fuse with the perineal muscles. Being a somatic voluntary muscle, the external sphincter is red in colour and is innervated by the pudendal nerve.

Figure 73.2 The disposition of the puborectalis muscle. Note how it maintains the rectoanal angle.

The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This plane is important as it contains intersphincteric anal glands (see below under The anal glands) and is also a route for the spread of pus, which occurs along the extensions from the longitudinal muscle layer. The plane can be opened up surgically to provide access for operations on the sphincter muscles.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. Most of the muscle continues caudally before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. Milligan and Morgan named the most medial of these septa, passing around the inferior border of the internal sphincter, the 'anal intermuscular septum'. As it descends, however, it gives off fibres that pass medially across the internal sphincter to reach the submucosal space, and laterally across the external sphincter and ischiorectal space to reach the fascia of the pelvic side walls. As well as providing a supportive mesh for the anal canal and other muscular components, its ramifications provide potential pathways for the spread of infection. During defaecation, its contraction widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle coat of the rectum, which has developed special properties and which is in a tonic state of contraction. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic (NANC) fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The epithelium and subepithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. Passing downwards, the mucous membrane becomes cuboidal and redder in colour (Figure 73.3), whereas above the anal valves it is plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to stratified squamous epithelium, which is the colour of parchment. This wavy junction constitutes the dentate line. The dentate line is a most important landmark both morphologically and surgically, representing the site of fusion of the proctodaeum and post-allantoic gut, and being the site of the crypts of Morgagni (synonym: anal crypts, sinuses). The latter are small pockets between the inferior extremities of the columns of Morgagni through which anal ducts that communicate with deeper placed anal glands open into the anal lumen. The squamous epithelium lining the lower anal canal is thin and shiny and is known as the anoderm; it differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. At the dentate line, the anoderm is attached more firmly to deeper structures. The mucosa and submucosa above the dentate line is uneven and thrown into folds, the so-called anal

Figure 73.3 The lining membrane of the anal canal (after Sir Clifford Naunton Morgan, London).

cushions. There are variations in the numbers and positions of these cushions, but there are usually three, corresponding to those seen in later life. These are described classically as occupying the left lateral, right posterior and right anterior positions, and they continue proximally as the primary rectal foldings. Secondary foldings (the rectal columns of Morgagni) lie both over and between the primary folds. This area is the caudal limit of the so-called epithelial transitional zone, below which the stratified squamous epithelium is richly innervated by sensory nerve endings serving several modalities including touch, pain and temperature. The bulk of the anal cushions themselves, situated in the upper part of the anal canal, receive only visceral afferent innervation and, although there is perception of stretching, sensitivity to noxious stimuli is much more blunted than distally.

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer and thereby supporting the mucosa itself. Parks described the increased density of fibres that insert into the mucosa of the anal crypts at the level of the dentate line, termed the 'mucosal suspensory ligament'. One feature of this structure is that it separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses, another is that the mucosa is more firmly tethered to underlying tissues at this level than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter, and indeed structures beyond the sphincter complex. With age, the smooth muscle component of this mesh is reduced and muscle fibres are gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

Blood supply

In addition to the meshwork support of the lining of the anal canal, the subepithelial space contains venous dilatations supported by the same fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids, but the seminal anatomical studies of Thomson have clarified this issue. Venous dilatations are seen in the submucosa both above and below the level of the dentate line; they are much more numerous above, although tend to be larger below. The historical description of the blood supply to the upper anal canal as constant, with bifurcation of the main trunk of the superior rectal artery into right and left branches and with subsequent division of the former into anterior and posterior divisions thereby determining the sites of haemorrhoids around the anal circumference, was questioned by Thomson. He demonstrated that the divisions of the superior rectal artery were not constant and that, furthermore, the anal submucosa in a proportion of his specimens received a blood supply from the middle and inferior rectal arteries. He was also able to show the presence of free communications between tributaries of the superior, middle and inferior rectal veins, as well as tiny direct arteriovenous

communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations (as well as the colour) is more arterial than venous.

Venous drainage

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portomesenteric venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins: they eventually join the internal iliac vein on each side.

Lymphatic drainage

Lymph from the upper half of the anal canal flows upwards to drain into the postrectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route (Summary box 73.1).

Summary box 73.1

Anal canal anatomy

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve
- Extensions from the longitudinal muscle layer support the sphincter complex
- The space between sphincters is known as the intersphincteric plane
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence
- The lower part of the anal canal is lined by sensitive squamous epithelium
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes

The anal glands

Anal glands (which are not vestigial remnants of sexual scent glands) may be found in the submucosa and intersphincteric space (Figure 73.4), and normally number between 0 and 10 in an individual. They drain via ducts into the anal sinuses at the level of the dentate line. Not all sinuses have a duct draining into them and, occasionally, more than one gland can discharge into the same sinus. Their function is unknown, although they secrete mucin (distinct from that secreted by the rectal epithe-

Figure 73.4 Intersphincteric anal gland lying between the voluntary muscle of the external sphincter and the longitudinal muscle. The internal sphincter is also seen. Reproduced with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.

lium), which perhaps lubricates the anal canal to ease defaecation. The importance of intersphincteric anal glands is that they are widely considered to be the potential source of anal sepsis, either acute, presenting as perianal, ischiorectal or even pelvic sepsis, or chronic, presenting as a cryptoglandular (non-specific) anal fistula.

EXAMINATION OF THE ANUS

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms, but it requires a relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jack-knife or knee–elbow positions may be used (Figure 73.5). The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A protective glove should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus et atrophicus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for examination under

Figure 73.5 The left lateral (a), knee–elbow (b) and lithotomy (c) positions for examination. Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.

anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; supralelevator induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze

are assessed. On withdrawal, the examining finger is inspected for the presence of mucus, blood or pus, and to identify stool colour.

Proctoscopy

Proctoscopy (Figure 73.6), performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal. Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below Management under Haemorrhoids) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

Sigmoidoscopy

Although sigmoidoscopy (see Chapter 72) is strictly an examination of the rectum, it should always be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently associated with an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment (Summary box 73.2).

Figure 73.6 Various types of proctoscope. Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.

Summary box 73.2

Examination of anal canal

- A rectal examination is essential for any patient with anorectal and/or bowel symptoms – ‘If you don’t put your finger in, you might put your foot in it’
- A proctosigmoidoscopy is essential in any patient with bowel symptoms, and particularly if there is rectal bleeding

PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR, AND SPECIAL INVESTIGATIONS

Anal continence and defaecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity. The sphincter mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory (Swash and Henry). Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function) can be measured by a variety of simple manometric techniques (Figure 73.7). The structural integrity of the sphincters can be visualised with endoluminal ultrasound (Figure 73.8), and neuromuscular function can be measured by assessment of conduction velocity along the pudendal nerve on each side, or, more painfully, by needle electromyogram (EMG) studies (Figures 73.9 and 73.10). In the elderly especially, but also in younger patients, disorders relating to rectal sensorimotor dysfunction can lead to ‘overflow’ of rectal contents through what may be an otherwise normal sphincter. The dynamics of defaecation can also be assessed radiologically by evacuation proctography, in which radio-opaque pseudo-stool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imag-

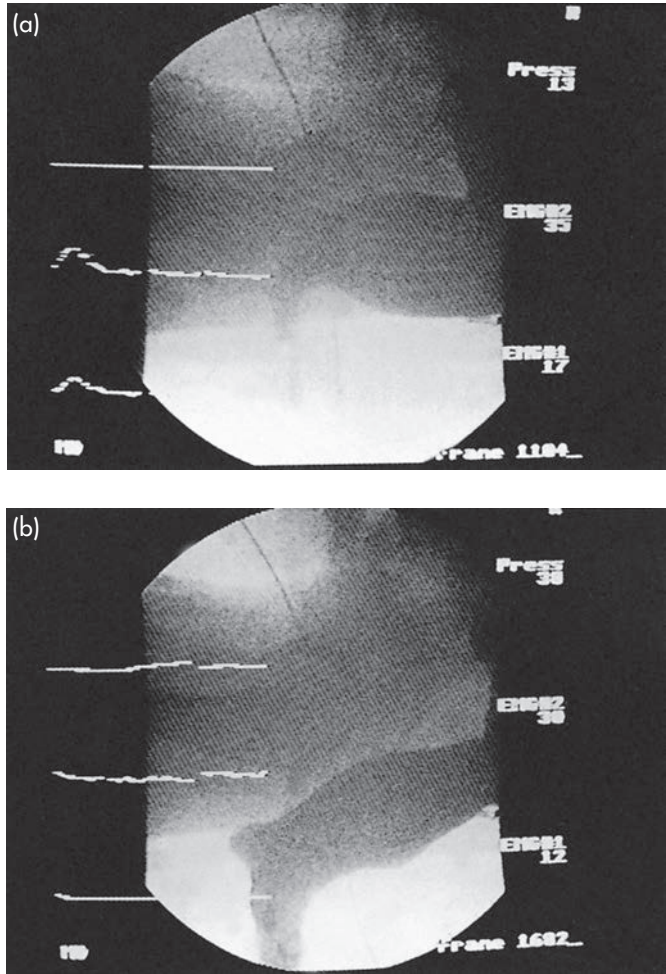

Figure 73.11 Integrated dynamic proctography. (a) At rest; (b) during evacuation. Visualisation of the rectum is achieved using barium-impregnated 'synthetic stool'. The effects of straining and evacuation on the electromyographic activity of the sphincter muscles and intrarectal pressure can be simultaneously recorded (Williams).

much more expensive modality of dynamic magnetic resonance proctography has become more widespread, although studies in which the subject is asked to evacuate in the supine position may be less physiological than those in which the subject adopts a sitting position within an open magnet. Results of all physiological and imaging tests have to be compared with a robust normal range and within the context of the patient's symptoms, and are used to guide rational rather than empirical treatment strategies.

CONGENITAL ABNORMALITIES

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endoderm-lined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts, dorsal (rectum) and ventral (urogenital sinus), by the downgrowth of a septum. The dorsal part of the cloacal membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the 8th week of embryonic life creates the anal canal.

Imperforate anus

Imperforate anus (see Chapter 8) (strictly, it should be anal 'agenesis' or 'atresia') has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems. In both sexes, low defects embrace rectoperineal fistula (Figure 73.12), covered anus and anal membrane. The most frequent defect in boys with imperforate anus is one in which the distal rectum is sited within the puborectalis sling, but terminates as a fistula into the bulbar urethra (Figure 73.13) (see also Chapter 8, Figure 6.32) or prostatic urethra above the main anal sphincter complex. Boys with a fistula into the bladder neck (a high defect) have the poorest prognosis because of the underdevelopment of the sacrum and pelvic and anal musculature. The most common defect in girls is a rectovestibular fistula, in which the fistula opens into the posterior vestibule (not the vagina) (Figure 73.12). The finding of a single perineal orifice indicates a persistent cloaca in which the rectum, vagina and urinary tract form a confluence (Figure 73.13); the longer the common channel, the greater the likelihood of more complex defects, including vaginal and uterine septation, duplication or atresia. An anterior anus, although not imperforate, is not fully located within the sphincter mechanism and is regarded as part of the spectrum of anorectal malformations (Figure 73.12).

Clinical management

Careful perineal examination will usually provide the most important clues about the neonate's type of malformation. The presence of meconium on the perineum indicates a low defect and meconium in the urine is evidence of a urinary tract fistula. During the first 24 hours, the baby should receive intravenous fluids and antibiotics, and should be evaluated for associated congenital anomalies. By 24 hours, the distal limit of air within the rectum, seen on a lateral prone radiograph,

indicates the distance between the rectal stump and perineum (Figure 73.14).

Treatment

Low anomalies with a perineal fistula can be treated by an anoplasty. More complex malformations require early colostomy, with definitive repair performed several months later. This may

Figure 73.13 More complex anorectal malformations. (a) Rectobulbar fistula; (b) cloacal malformation. Courtesy of Alberto Pena and Springer-Verlag. From *Atlas of surgical management of anorectal malformations* by Alberto Pena, 1990. Copyright Springer-Verlag.

involve posterior sagittal anorectoplasty (PSARP, Pena) with or without transabdominal mobilisation of the left colon and division of any communication with the urinary tract. In girls with a cloaca and long common channel, urinary and vaginal reconstruction is also required. Postoperatively, a programme of anal dilatation is instituted, and any residual colostomy is closed at a later date. Ultimate bowel function (voluntary bowel movements, continence, constipation) is related to the type of anorectal abnormality and the presence of associated defects, especially sacral (Summary box 73.3).

Summary box 73.3

Imperforate anus

- A rare congenital disorder
- Classified as being high or low depending on the site of the rectal termination in relation to the pelvic floor
- Low defects: relatively easy to correct, but prone to constipation
- High defects: more difficult to correct and prone to faecal incontinence

Figure 73.14 Lateral prone shoot-through radiograph of a neonate with (a) low and (b) high anorectal malformation. A radio-opaque marker has been placed on the anal dimple (courtesy of Mark D Stringer, Leeds, UK).

Post-anal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a post-anal dermoid cyst. Hidden in the hollow of the sacrum, it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defaecation. The cyst is easily palpable on rectal examination.

Differential diagnosis

Especially in a child, an anterior sacral meningocele must be excluded. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a post-anal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the

rectum may cause a flow of sebaceous material, and injection of contrast media followed by radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment

Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts, it is necessary to remove the coccyx to gain access. The coccyx should also be removed *en bloc* in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma.

Post-anal dimple

A post-anal dimple (synonym: fovea coccygea) is a dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit. It is noticed from time to time in the course of a clinical examination and is of no consequence.

Pilonidal sinus

The term 'pilonidal sinus' describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen. A common affliction among the military, it has been referred to as 'jeep disease'.

Aetiology and pathology

Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms of development are speculative. Evidence that supports the acquired theory of origin of pilonidal sinuses can be summarised as follows:

- Interdigital pilonidal sinus is an occupational disease of hairdressers, the hair within the interdigital cleft or clefts being from the customers. Pilonidal sinuses of the axilla and umbilicus have also been reported.
- The age incidence of the appearance of pilonidal sinus (82 per cent occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.
- Hair follicles have almost never been demonstrated in the walls of the sinus.
- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.
- The disease mostly affects men, in particular hairy men.
- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttock friction and shearing forces in that area allows shed hair or broken hairs which have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa), the sinus runs cephalad. Carcinoma arising

in chronic pilonidal disease has been described, but is exceedingly rare.

Clinical features

The condition is seen much more frequently in men than in women, usually after puberty and before the fourth decade of life, and is characteristically seen in dark-haired individuals rather than those with softer blond hair (Oldham). Patients complain of intermittent pain, swelling and discharge at the base of the spine, but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously or which have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx.

Conservative treatment

As the natural history of the condition is usually one of regression, in those whose symptoms are relatively minor, simple cleaning out of the tracks and removal of all hair, with regular shaving of the area and strict hygiene, may be recommended.

Treatment of an acute exacerbation (abscess)

If rest, baths, local antiseptic dressings and the administration of a broad-spectrum antibiotic fail to bring about resolution, the abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curettage of granulation tissue and hair. This procedure may or may not be associated with complete resolution.

Surgical treatment of chronic pilonidal disease

The multitude of surgical procedures advocated to eradicate pilonidal disease, combined with the lack of prospective trials, attests to the lack of overall superiority of one method over the others. Time spent off work and perceived recurrence rates, but more usually surgeon preference, influence the choice of method, which includes the laying open of all tracks with or without marsupialisation, the excision of all tracks with or without primary closure, and the excision of all tracks and then closure by some other means designed to avoid a midline wound (Z-plasty, Karydak's procedure (Figure 73.15)). Bascom's procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (Figure 73.16), and excision and closure of the midline pits (Figure 73.17). The lateral wound is left open (Figure 73.18). Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound.

Recurrent pilonidal sinus

Three possibilities account for this disappointment:

- part of the sinus complex has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- there is persistence of a midline wound caused by shearing forces and scarring; in this situation, revisional surgery may include re-excision followed by wound closure and

obliteration of the natal cleft either by myocutaneous rotational buttock flap or cleft closure (Bascom).

ANAL INCONTINENCE

Aetiology

As continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract, the risk factors for anal incontinence are many (Summary box 73.4). Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anal surgery; and careful clinical examination (in the elderly, incontinence is often one of overflow secondary to rectal impaction, and proctitis may lead to such an irritable rectum that even the strongest sphincter is occasionally overwhelmed). A combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management.

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the

Figure 73.16 Bascom's technique for pilonidal sinus: 1.

sphincter muscles, neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage), or a combination of the two. The most common causes of sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise).

Summary box 73.4**Causes of anal incontinence****Congenital/childhood**

- Anorectal anomalies
- Spina bifida
- Hirschsprung's disease
- Behavioural

Acquired/adulthood

- Diabetes mellitus

 - Surgery for fissure
 - Rectal disimpaction
- Obstetric events

General

- Ageing
- Dependence of nursing care
- Obesity
- Psychobehavioural factors
- Intellectual incapacity
- Drugs:
 - Primary constipating and laxative agents
 - Secondary effects

In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.

Operations to reunite divided sphincter muscles

In situations in which there is a discrete disruption of the sphincters, the ends of the divided muscle are found and reunited by a double overlap repair (Figure 73.19).

Operations to reef the external sphincter and puborectalis muscle

If the sphincter muscles are stretched and patulous (as they often are in old age and in cases of rectal prolapse) they may be tightened by a post-anal repair, which, through the use of darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Figure 73.20), aims to recreate the anorectal angle and to restore length to the anal canal and strength to the anal sphincter. The approach is usually through the intersphincteric plane. The operation is now much less popular because long-term outcomes have been reported as poor.

Operations to augment the anal sphincters

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial

Figure 73.19 Direct sphincter repair in which (a) the sphincter defect is excised and (b) the remaining muscle is overlapped. Redrawn with permission from Mann CV, Glass RE. *Surgical treatment of anal incontinence*. New York: Springer, 1991.

Figure 73.20 Post-anal repair in which (a) the sphincter muscle is plicated posterior to the anal canal, thus restoring the anorectal angle. (b) The completed repair. Redrawn with permission from Mann CV, Glass RE. *Surgical treatment of anal incontinence*. New York: Springer, 1991.

sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatiguable slow-twitch muscle by an implanted pacemaker (Williams) (Figure 73.21). Because of its magnitude, this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence; it is effective in approximately 60 per cent of patients in the long term. A simpler means of augmenting the sphincter, developed initially for urinary incontinence, is the placement of an inflatable silastic cuff around the anal canal. When evacuation is required, the cuff is deflated by squeezing a small balloon positioned in the scrotum or labia, the balloon being attached to a subcutaneous reservoir (Figure 73.22). However, because this device is a foreign body that exerts pressure on the bowel wall, erosion and infection have been found to be common problems. To reduce the risk of septic complications the operation should be covered by antibiotics active against both aerobic and anaerobic organisms. Paradoxically, all of these methods used to treat incontinence may be associated with difficulties in rectal evacuation.

More recently, again as a result of its use in urinary incontinence, sacral nerve stimulation has been used to treat faecal incontinence, with encouraging short- and medium-term results.

Figure 73.21 (a) The electrically stimulated gracilis neosphincter or dynamic graciloplasty. (b) Hand-held radiotelemetry controller, which allows the patient to turn the stimulator on and off.

Figure 73.22 Artificial bowel sphincter. A cuff is placed around the anal canal. An inflatable pump control assembly is placed in the scrotum and the balloon reservoir is placed under the symphysis pubis.

Rather than any direct action on sphincter strength, this technique appears to work by sensorimotor neurophysiological modulation of the hindgut through electrical stimulation of the sacral nerve roots via a needle positioned through one of the posterior sacral foramina (Figure 73.23). A potential advantage of this technique is its relatively non-invasive nature, as well as the fact that its effects can be tested by temporary stimulation using an external stimulator before the expensive permanent pacemaker is implanted. A much cheaper and less invasive novel technique to treat faecal incontinence, again mediated through neuromodulation is percutaneous posterior tibial nerve stimulation (PTNS) whereby the tibial nerve at the ankle is electrically stimulated once per week for several minutes. The course of treatment is usually for 12 weeks and is administered on an outpatient basis. Results from prospective comparative studies are eagerly awaited.

For some patients, and in those in whom quality of life remains poor despite attempts at restoring continence, a permanent stoma can provide relief from a condition which is both disabling and socially isolating.

Figure 73.23 Diagram showing the placement of the electrode through a sacral foramen in sacral nerve stimulation.

ANAL FISSURE

Definition

An anal fissure (synonym: fissure-in-ano) is a longitudinal split in the anoderm of the distal anal canal (Figure 73.24), which extends from the anal verge proximally towards, but not beyond, the dentate line.

Aetiology

The cause of an anal fissure, and particularly the reason why the posterior midline is so frequently affected, is not completely understood. Classically, acute anal fissures arise from the trauma caused by the strained evacuation of a hard stool or, less commonly, from the repeated passage of diarrhoea. The location in the posterior midline perhaps relates to the

Figure 73.24 The appearance of an anal fissure. If the buttocks are gently parted, the presence of an anal fissure can usually be detected as an ulcer of variable depth with the skin tag and an anal papilla. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, colon and rectum*, 2nd edn. Philadelphia, PA: WB Saunders, 1999.

exaggerated shearing forces acting at that site at defaecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is much more common in women and may arise following vaginal delivery. Perpetuation and chronicity may result from repeated trauma, anal hypertonicity and vascular insufficiency, either secondary to increased sphincter tone or because the posterior commissure is less well perfused than the remainder of the anal circumference.

Clinical features

Simple epithelial splits, because of their location involving the exquisitely sensitive anoderm, acute anal fissures are characterised by severe anal pain associated with defaecation. This usually resolves spontaneously after a variable time only to recur at the next evacuation, as well as the passage of fresh blood, normally noticed on the tissue after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent upon attempts at healing and breakdown), between which lies the slightly indurated anal ulcer overlying the fibres of the internal sphincter. When chronic, patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. Men and women are affected equally. Anterior fissures account for about 10 per cent of those encountered in women, but only 1 per cent in men. A fissure sited elsewhere around the anal circumference or with atypical features should raise the suspicion of a specific aetiology, and failure of adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn's disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, *Chlamydia*, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi's sarcoma, B-cell lymphoma) and squamous cell carcinoma (Summary box 73.5).

Summary box 73.5**Anal fissure**

- Acute or chronic
- Ischaemic ulcer in the midline of the anal canal
- Ectopic site suggests a more sinister cause
- Symptoms:
 - Pain on defaecation
 - Bright-red bleeding
 - Mucous discharge
 - Constipation

Treatment

After confirmation of the diagnosis in the clinic or under anaesthesia, with exclusion of secondary causes of anal ulceration, conservative management should result in the healing of almost all acute and the majority of chronic fissures. Emphasis must be placed on normalisation of bowel habits such that the passage of stool is less traumatic. The addition of fibre to the diet to bulk up the stool, stool softeners and adequate water intake are simple and helpful measures. Warm baths and topical local anaesthetic agents relieve pain; however, providing patients with anal dilators is usually associated with low compliance and consequently little effect. The mainstay of current conservative management is the topical application of pharmacological agents that relax the internal sphincter, most commonly nitric oxide donors (Scholefield); by reducing spasm, pain is relieved, and increased vascular perfusion promotes healing. Such agents include glyceryl trinitrate (GTN) 0.2 per cent applied four times per day to the anal margin (although this may cause headaches) and diltiazem 2 per cent applied twice daily.

Operative measures

Historically, under regional or general anaesthesia, forceful manual (four- or eight-digit) sphincter dilatation was used to reduce sphincter tone; however, this was achieved in an uncontrolled fashion with potential disruption at multiple sites of the internal (and even external) sphincter. The risk of incontinence following this procedure has now made it unpopular, although more conservative controlled stretching is still practised in young men with very high sphincter tone.

Fissure healing can also be achieved by a posterior division of the exposed fibres of the internal sphincter in the fissure base, but this is associated with prolonged healing, as well as passive anal leakage thought mainly to be due to the resulting keyhole gutter deformity; however, it may be indicated if there is an associated intersphincteric fistula.

Lateral anal sphincterotomy

In this operation, the internal sphincter is divided away from the fissure itself – usually either in the right or the left lateral positions (Notaras). The procedure can be carried out using an open or a closed method, under local, regional or general anaesthesia, and with the patient in the lithotomy or prone jack-knife position. The distal internal sphincter is palpated with a bivalved speculum at the intersphincteric groove. In the closed

method, a small longitudinal incision is made over this, and the submucosal and intersphincteric planes are carefully developed to allow precise division of the internal sphincter with a knife or scissors to the level of the apex of the fissure; the wound is then closed with absorbable sutures. Alternatively, either plane can be entered using a scalpel (No. 11 blade), with the blade advanced parallel to the sphincter and then rotated such that the sharp edge faces the internal sphincter, which can then be divided along its distal third. Pressure should be applied to the wound for a few minutes to prevent haematoma formation. In the open technique, the anoderm overlying the distal internal sphincter is divided longitudinally to expose the sphincter, which is divided, and the wound is closed with absorbable sutures. Although the fissure needs no specific attention, problematic papillae and external tags can be excised concomitantly.

Early complications of sphincterotomy include haemorrhage, haematoma, bruising, perianal abscess and fistula. Despite low recurrence rates, the most important complication is incontinence of a variable nature and severity, which may affect up to 30 per cent of patients, particularly women, who have weaker, shorter sphincter complexes and in whom there may already have been covert sphincter compromise incurred by childbirth.

Anal advancement flap

The recognition of the risk to continence following internal sphincterotomy has led some to advocate a different approach, especially in women and those with normal or low resting anal pressures, developed from the treatment of anal stenosis. After excision of the edges of the fissure and, if necessary, its base overlying the internal sphincter, an inverted house-shaped flap of perianal skin is carefully mobilised on its blood supply and advanced without tension to cover the fissure, and then sutured with interrupted absorbable sutures (Figure 73.25). The patient is maintained on stool softeners and bulking agents postoperatively, and usually also on topical sphincter relaxants; minor breakdown of one anastomotic edge does not herald ultimate failure (Summary box 73.6). The technique appears to work irrespective of sphincter hypertonicity or patient gender.

Figure 73.25 Mobilised skin flap prior to suturing intra-anally over the debrided and freshened posterior fissure base.

Summary box 73.6**Treatment of an anal fissure**

- Conservative initially, consisting of stool-bulking agents and softeners, and chemical agents in the form of ointments designed to relax the anal sphincter and improve blood flow
- Surgery if above fails, consisting of lateral internal sphincterotomy or anal advancement flap

Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60 per cent of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defaecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defaecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of 'cryptitis' may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and it is also said to afflict young doctors. The pain may be unbearable – it is possibly caused by segmental cramp in the pubococcygeus muscle. It is unpleasant and incurable, but is fortunately harmless and gradually subsides. If patients have frequent attacks, they may benefit from amitriptyline. Salbutamol inhalers have been suggested as treatment for acute attacks. A more chronic form of the disease has been termed the 'levator syndrome' and can be associated with severe evacuatory dysfunction. Biofeedback techniques have been used to help such patients; in the past, some surgeons tried severing the puborectalis muscle, but this can cause incontinence and should never be carried out.

HAEMORRHOIDS

The prevalence of haemorrhoids when patients are assessed proctoscopically far outweighs the prevalence of symptoms, and the term should only be used when patients have symptoms referable to them. Occasionally, patients with portal

hypertension develop rectal varices, but these should not be confused with haemorrhoids as the consequences may be disastrous. Internal haemorrhoids (Greek: *haima*, blood; *rhoos*, flowing; synonym: piles, Latin: *pila*, a ball) are symptomatic anal cushions and characteristically lie in the 3, 7 and 11 o'clock positions (with the patient in the lithotomy position). In addition, haemorrhoids may be observed between the main pile masses, in which case they are internal haemorrhoids at the secondary position. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are not true haemorrhoids; they are usually only recognised as a result of a complication, which is most typically a painful solitary acute thrombosis. External haemorrhoids associated with internal haemorrhoids ('interoexternal piles') result from progression of the latter to involve both haemorrhoidal plexuses and are best thought of as being external extensions of internal haemorrhoids. Secondary internal haemorrhoids arise as a result of a specific condition, although the mechanisms involved may be the same as those involved in the formation of primary internal haemorrhoids. The most important cause, albeit relatively uncommon, is carcinoma of the anorectum (Figure 73.26), but there are many other causes, which may be categorised as follows:

- local, e.g. anorectal deformity, hypotonic anal sphincter;
- abdominal, e.g. ascites;
- pelvic, e.g. gravid uterus, uterine neoplasm (fibroid, carcinoma of the uterus or cervix), ovarian neoplasm, bladder carcinoma;
- neurological, e.g. paraplegia, multiple sclerosis.

Figure 73.26 Carcinoma of the rectum associated with haemorrhoids, a not infrequent diagnostic pitfall.

Primary internal haemorrhoids

Theories of development

Portal hypertension and varicose veins

Misconceptions concerning the vascular anatomy of the anal canal (specifically the lack of appreciation of communications between portal and systemic systems and the 'normality' of venous dilatations) led to theories of development of primary internal haemorrhoids that lasted for several centuries. Man's upright posture (we know little about haemorrhoidal problems in animals), lack of valves in the portal venous system and raised abdominal pressure were thought to contribute to the development of anal varicosities. If raised portal venous pressure were indeed the cause, one would expect a high incidence in subjects suffering from portal hypertension; however, although such patients have a higher incidence of anorectal varices, these are a separate anatomical and clinical entity from haemorrhoids, which are seen no more frequently than in those without cirrhosis, portal hypertension and oesophageal varices.

Other vascular causes

Historically, some considered haemorrhoids to be haemangiomas or to result from changes in the erectile tissue that forms part of the continence mechanism, such as hyperplasia of the 'corpus cavernosum recti'.

Infection

Repeated infection of the anal lining, secondary to trauma at defaecation, has been postulated as a cause of weakening and erosion of the walls of the veins of the submucosa. This hypothesis is difficult to accept, as one of the truly incredible properties of the anal canal is its resistance to infection, as well as the ability of its mucosa to heal after surgical intervention despite the torrent of micro-organisms passing over it.

Diet and stool consistency

Much emphasis has been placed on the role of constipation in the development of haemorrhoids and, indeed, much of the management of sufferers involves attempts to 'normalise' bowel habits. A fibre-deficient diet results in a prolonged gut transit time, which is associated with the passage of smaller, harder stools that require more straining to expel. The presence of a hard faecal mass in the rectum could obstruct venous return, resulting in engorgement of the anal veins with the act of straining at stool or sitting for prolonged periods on the lavatory with a relaxed perineum, causing a disturbance of vascular flow. However, the epidemiological pattern of constipation is different from that of haemorrhoidal disease and, indeed, an association has been demonstrated between haemorrhoids and diarrhoeal disorders.

Anal hypertonia

The association between raised anal canal resting pressure and haemorrhoids is well known, but whether anal hypertonia causes symptoms attributable to haemorrhoids or whether anal cushion hypertrophy causes anal hypertonia is a subject of debate. The fact that surgical haemorrhoidectomy restores resting pressures to the normal range is not absolute evidence that the pile masses themselves are the cause of the hypertonia. It should be remembered, however, that there are a significant proportion of

patients who suffer haemorrhoidal symptoms in whom the anal canal is relatively patulous, and there is mucosal prolapse, which is associated with perineal descent and pudendal neuropathy.

Ageing

In contrast to the anal cushion of early life, with age, the supporting structures show a higher proportion of collagen than muscle fibres and are fragmented and disorganised. Presumably, these changes arise over time with continued use of the anal canal for defaecation; however, similar changes are noted histologically in surgically excised haemorrhoids in younger patients.

Current view

Shearing forces acting on the anus (for a variety of reasons) lead to caudal displacement of the anal cushions and mucosal trauma. With time, fragmentation of the supporting structures (a normal consequence of ageing, but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defaecation.

Clinical features

Bleeding, as the name haemorrhoid implies, is the principal and earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. Very rarely, the bleeding may be sufficient to cause anaemia. Pain is not commonly associated with the bleeding and its presence should make the clinician alert to the possibility of another diagnosis; however, pain may result from congestion of pile masses below a hypertonic sphincter. Piles associated with bleeding alone are called first-degree haemorrhoids (Summary box 73.7).

Summary box 73.7

Haemorrhoids: clinical features

- Haemorrhoids or piles are symptomatic anal cushions
- They are more common when intra-abdominal pressure is raised, e.g. in obesity, constipation and pregnancy
- Classically, they occur in the 3, 7 and 11 o'clock positions with the patient in the lithotomy position
- Symptoms of haemorrhoids:
 - bright-red, painless bleeding
 - mucous discharge
 - prolapse
 - pain only on prolapse

Patients may complain of true 'piles', lumps that appear at the anal orifice during defaecation and which return spontaneously afterwards (second-degree haemorrhoids), piles that have to be replaced manually (third-degree haemorrhoids) (Figure 73.27) or piles that lie permanently outside (fourth-degree haemorrhoids). By this stage, there is often a significant cutaneous component to the pile masses, which arise through repeated congestion and oedema. In addition to the main symptoms of pain and prolapse, patients may complain of anal irritation, which may occur as a result of mucus secretion from the caudally displaced rectal mucosa, minor leakage through a now imperfect anal seal or difficulties in cleaning after defaecation because of the irregularity of the anal verge (Summary box 73.8).

Figure 73.27 Third-degree haemorrhoids (courtesy of CV Mann, The Royal London Hospital, London, UK).

Summary box 73.8

Four degrees of haemorrhoids

- First degree – bleed only, no prolapse
- Second degree – prolapse, but reduce spontaneously
- Third degree – prolapse and have to be manually reduced
- Fourth degree – permanently prolapsed

Complications

Profuse haemorrhage is uncommon. The bleeding mainly occurs externally but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances, the rectum is found to contain blood (Summary box 73.9).

Summary box 73.9

Complications of haemorrhoids

- Strangulation and thrombosis (Figure 73.28)
- Ulceration
- Gangrene
- Portal pyaemia
- Fibrosis

Treatment of complications

- **Strangulation, thrombosis and gangrene.** In these cases, it was formerly believed that surgery would promote portal pyaemia. However, if adequate antibiotic cover is given from the start, this is not found to be so, and immediate surgery can be justified in many patients. The other risk if surgery is performed at this stage, that of postoperative stenosis, results

in some surgeons reviewing the situation much later and carrying out haemorrhoidectomy only if necessary. Besides adequate pain relief, bed rest with frequent hot baths and warm or cold saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3–4 days (the authors' preference is shrinkage through external application of small bags of frozen peas). An anal dilatation technique has in the past been used as an alternative treatment to surgery for painful 'strangulated' haemorrhoids (Figure 73.28). However, because of the risk of incontinence this is no longer advised.

- **Severe haemorrhage.** The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such causes are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually suffice. However, after adequate blood replacement, ligation and excision of the piles may be required.

Management

Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include attempts at normalising bowel and defaecatory habits: only evacuating when the natural desire to do so arises, adopting a defaecatory position to minimise straining, and the addition of stool softeners and bulking agents to ease the defaecatory act. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defaecation. Suppositories are also useful.

In those with first- or second-degree piles whose symptoms are not improved by conservative measures, injection sclerotherapy (Mitchell), the submucosal injection of 5 per cent phenol in arachis oil or almond oil, may be advised. Any invasive treatment, however, must be with full agreement of the patient, who should be informed of the potential risks of such interventions. The aim is to create fibrosis, cause obliteration of the vascular channels and hitch up the anorectal mucosa.

Figure 73.28 An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with fibrofatty covering.

With the awake patient in the left lateral position and under direct vision with a proctoscope, about 5 mL of sclerosant is injected into the apex of the pile pedicle (Figure 73.29) using a (now) disposable needle and syringe (Figure 73.30). The procedure is repeated for each pile and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the mucosa, which turns

Figure 73.29 Correct site (cross) for injecting a haemorrhoid (after WB Gabriel, London, UK).

Figure 73.30 Gabriel's syringe (a) has now been replaced by disposable syringes (b).

white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have disastrous consequences, including pelvic sepsis, prostatitis, impotence and rectovaginal fistula.

For more bulky piles, banding has been shown to be efficacious, but it is associated with more discomfort. The Barron's bander is a commonly available device used to slip tight elastic bands onto the base of the pedicle of each haemorrhoid (Figure 73.31). The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. As with sclerotherapy, three piles may be treated at one session, and the process may be repeated after several weeks if necessary. The techniques of cryotherapy (Lloyd Williams) and infrared photocoagulation (Leicester) are not often used nowadays.

Operation

Indications

The indications for haemorrhoidectomy include:

- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- fibrosed haemorrhoids;
- interoeexternal haemorrhoids when the external haemorrhoid is well defined.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and, if indicated, biopsy are necessary. The other strong indication for surgery is haemorrhoidal bleeding sufficient to cause anaemia. Beyond these, the indications summarised above are more relative than absolute, because in these situations surgery aims simply to improve symptoms and, of course, is not without risk. For instance, elderly multiparous women with hypotonic sphincters who are just continent before haemorrhoidectomy may find that the procedure results in frank incontinence, a far worse condition than that for which they originally sought help.

Kenneth Lloyd Williams, deceased, surgeon, The Royal United Hospitals, Bath, UK.

Roger James Leicester, surgeon, St George's Hospital, London, UK.

Technique

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum is administered. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. The perianal skin is shaved and a formal examination performed. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK and is known as the Milligan–Morgan operation – named after the surgeons who described it. The closed technique is the popular technique in the United States. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

- **Open technique.** The anoderm and subcutaneous tissues between the pile masses may be injected with dilute adrenaline (epinephrine, 1:300 000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the piles and traction

exerted to reveal the internal components, which are also grasped by artery forceps. When held out by the assistant, these pairs of artery forceps form a triangle (Figure 73.32a). The operator takes the left lateral pair of artery forceps in the palm of the hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way, traction is applied to the skin of the anal margin. With scissors or cutting diathermy, a V-shaped cut is made through the skin and those fibres inserting into it around the skin-holding artery forceps. Traction by both operator and assistant, combined with careful dissection, will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (Figure 73.32b). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (Figure 73.32c), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are significant secondary haemorrhoids under these bridges, they can

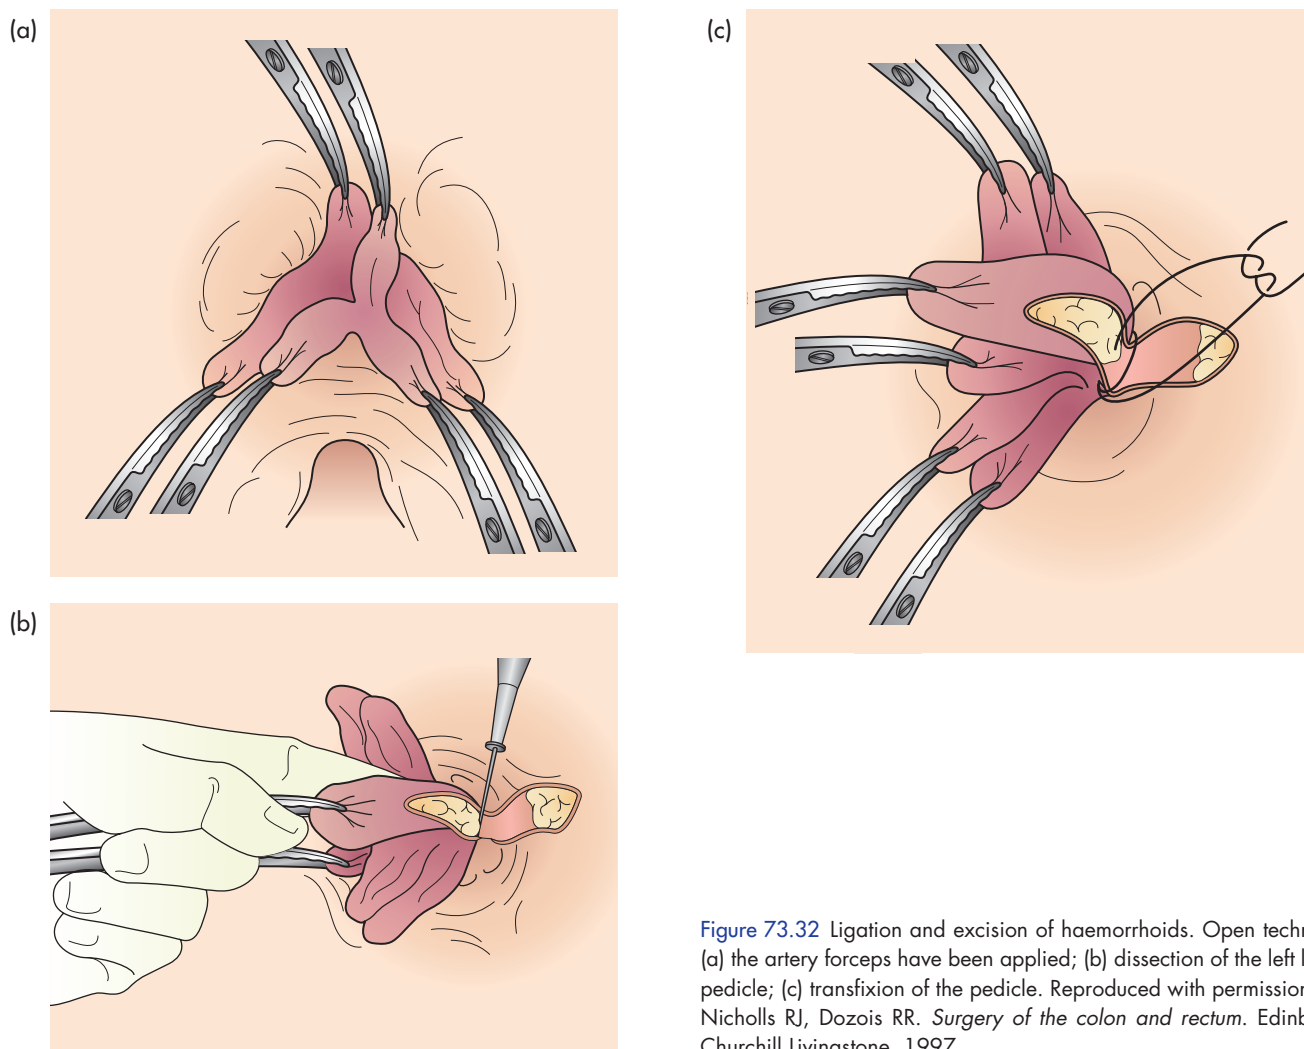

Figure 73.32 Ligation and excision of haemorrhoids. Open technique: (a) the artery forceps have been applied; (b) dissection of the left lateral pedicle; (c) transfixion of the pedicle. be filleted out by scissor dissection. Haemostasis must be absolute at the end of the procedure, when a soft absorbable anal dressing is inserted. The margins of the skin wounds are trimmed so as not to leave overhanging edges (Figure 73.33). Bleeding subcutaneous arteries having been secured, the areas denuded of skin are dressed with three pieces of petroleum jelly gauze. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

- **Closed technique.** The haemorrhoid is excised, together with the overlying mucosa, as illustrated in Figure 73.34a. The haemorrhoid is dissected carefully from the underlying sphincter and haemostasis is achieved. The pedicle is transfixed and ligated with 3/0 Vicryl or Dexon. Any residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucosal defect is then closed completely with a continuous suture using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.

With the aim of symptom relief but preservation of the anal cushions, the technique of stapled haemorrhoidopexy (Longo), which utilises a purpose-designed stapling gun (PPH, Ethicon Inc.), has recently been described. This procedure excises a strip of mucosa and submucosa (together with the vessels travelling within them) circumferentially, well above the dentate line. Activation of the gun also simultaneously repairs the cut mucosa and submucosa by stapling the edges together (Figure 73.35). This procedure is quick to perform, and controlled trials sug-

Figure 73.33 The appearance of the anus at the conclusion of the operation. (Note that to avoid stricture formation, it is necessary to ensure that a bridge of skin and mucous membrane remains between each wound.) gest that it is less painful and less traumatic than conventional haemorrhoidectomy and, at least in the short term, it seems to be equally efficacious. However, evidence is emerging that the technique is associated with higher recurrence rates than following conventional haemorrhoidectomy, and associated with more additional surgery. The patient, after counselling, may choose to accept a higher recurrence rate to take advantage of the short-term benefits, or not (Summary box 73.10).

Figure 73.35 Stapled haemorrhoidectomy. (a) The purse-string suture is placed several centimetres above the dentate line. (b) The anvil of the fully opened stapling gun is inserted endoanally so that it is above the purse-string suture, which is then tied around the shaft of the gun. The gun is closed and fired. (c) After firing, a 3–4 cm strip of mucosa and submucosa containing the haemorrhoids is excised and the mucosal edges are simultaneously stapled together.

Summary box 73.10

Treatment of haemorrhoids

- Symptomatic – advice about defaecatory habits, stool softeners and bulking agents
- Injection of sclerosant
- Banding
- Transanal haemorrhoidal dearterialisation/haemorrhoidopexy
- Haemorrhoidectomy

Transanal haemorrhoidal dearterialisation

Transanal haemorrhoidal dearterialisation (THD) is used for the treatment of second- and third-degree haemorrhoids. Some have recently advocated transanal Doppler-guided ligation of those vessels feeding the haemorrhoidal masses, to which others have added suture ‘mucopexy’ to deal with any prolapse. Long-term outcomes are unknown, but recurrence rates for fourth-degree haemorrhoids (certainly when additional procedures are not incorporated) are high.

Postoperative care

In these days of economic stringencies, the patient is discharged from hospital within a day or two of the operation. In many countries, the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily together with appropriate analgesia. There is some evidence that a 5-day course of oral metronidazole may reduce pain. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

Postoperative complications

Postoperative complications may be early or late. Early complications include pain, which may require opiate analgesia; retention of urine, especially in men, which rarely may need relief by catheterisation; and reactionary haemorrhage, which is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed, but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum are packed.

Late postoperative complications include:

- Secondary haemorrhage. This is uncommon, occurring about the 7th or 8th day after operation. It is usually controlled by morphine but, if the haemorrhage is severe, an anaesthetic should be given and the bleeding controlled.
- Anal stricture, which must be prevented at all costs. A rectal examination at the postoperative review will indicate whether stricturing is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.
- Anal fissures and submucous abscesses.

- Incontinence, especially if there has been inadvertent damage to the underlying internal sphincter. Although uncommon, this is obviously a very serious problem that is difficult to treat (Summary box 73.11).

Summary box 73.11

Complications of haemorrhoidectomy

- Early
 - Pain
 - Acute retention of urine
 - Reactionary haemorrhage
- Late
 - Secondary haemorrhage
 - Anal stricture
 - Anal fissure
 - Incontinence

External haemorrhoids

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a 'perianal haematoma'. It presents as a sudden onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight (Figure 73.36). The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours, the clot may be evacuated under local anaesthesia. Untreated it may

Figure 73.36 A thrombosed external haemorrhoid that has burst. There is also a mucosal prolapse, which is separate from the cutaneous lesion.

resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude, or continue bleeding. In the majority of cases, resolution or fibrosis occurs. Indeed, this condition has been called 'a 5-day, painful, self-curing lesion' (Milligan).

PRURITUS ANI

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist.

Causes

The causes are numerous. A useful mnemonic is 'pus, polypus, parasites, piles, psyche':

- **Lack of cleanliness**, excessive sweating and wearing rough or woollen underclothing.
- **An anal or perianal discharge** that renders the anus moist. The causative lesions include an anal fissure, fistula-in-ano, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.
- **A vaginal discharge**, especially caused by *Trichomonas vaginalis* infection.
- **Parasitic causes**. Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting – 'parasites lost, parasites regained'. Scabies and pediculosis pubis may infest the anal region.
- **Epidermophytosis** is a common cause, especially if the skin between the toes is also infected; microscopic and cultural examinations are essential. Half-strength Whitfield's ointment quickly gives relief and is the sheet anchor of treatment.
- **Allergy** is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.
- **Skin diseases** localised to the perianal skin: psoriasis, lichen planus and contact dermatitis.
- **Bacterial infection**, such as intertrigo resulting from a mixed bacterial infection. Erythrasma caused by *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultraviolet light, which induces a pink fluorescence.
- **A psychoneurosis**. It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain-pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.
- **Diabetes** can sometimes present with pruritus ani, and the urine should be tested in all patients.

Treatment

The cause is treated. Symptomatic treatment includes the following:

- **Hygiene measures**. Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by water alone,

and the area pat-dried rather than rubbed. These measures alone, combined with wearing cotton underwear and the application of calamine lotion or zinc and castor oil, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.

- **Hydrocortisone.** In patients with dermatitis, and only in patients with dermatitis, the topical application of 0.5 or 1 per cent prednisolone cream is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which case 5 per cent lidocaine hydrochloride (Xylocaine) ointment can be substituted for a time.
- **Strapping the buttocks** keeps moist opposing surfaces apart, but is not well tolerated. If the moistness originates from anal discharge, a cotton wool anal plug will seal the anal orifice.

Operative treatment

This may be necessary for a concomitant lesion of the anorectum that is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated (Summary box 73.12).

Summary box 73.12

Pruritus ani

- Common
- Numerous causes including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

ANORECTAL ABSCESSSES

Acute sepsis in the region of the anus is common. A fundamental distinction that has to be made is whether the sepsis is in that area by chance (simple boil, skin appendage infection) or whether it has arisen as a consequence of the presence of the anorectum, specifically the anal glands. Overall, anorectal sepsis is more common in men than women, although infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that, upon infection of a gland, pus, which travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischiorectal abscess or, rarely, superiorly above the anorectal junction to form a supralelevator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischiorectal or pararectal supralelevator (Figure 73.37). Sepsis unrelated to anal gland infection may occur at the same or at other sites (Figure 73.38), including submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolve spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischiorectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal supralelevator sepsis originating in pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn's disease, may be the cause. Similarly,

Figure 73.37 Axial magnetic resonance imaging (MRI) scan (STIR sequence) showing posterior horseshoe spread of sepsis within the intersphincteric space.

Figure 73.38 Diagram showing the spaces in relation to the anus and types of anorectal abscess in coronal section: A, pelvirectal supralelevator space; B, ischiorectal space; C, perianal or superficial ischiorectal space; D, marginal or mucocutaneous space; E, submucous space; F, anorectal intermuscular (intersphincteric) space; 1, pelvirectal supralelevator abscess; 2, submucous abscess; 3, ischiorectal abscess; 4, marginal abscess; 5, perianal abscess; 6, intersphincteric abscess. Reproduced with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.

patients with generalised disorders, such as diabetes and acquired immunodeficiency syndrome (AIDS), may present with an anorectal abscess; in these patients, abscesses may run an aggressive course.

Presentation

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day)

history of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot tender perianal swelling. Patients with infection in the larger fatty-filled ischiorectal space, in which tissue tension is much lower, usually present later, with less well-localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender supralelevator induration palpable on digital examination above the anorectal junction.

Differential diagnosis

The only conditions with which an anorectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin's gland or Cowper's gland.

Management

Management of acute anorectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischiorectal sepsis (with an incidence of 60 and 30 per cent, respectively), drainage is through the perineal skin, usually through a cruciate incision over the most fluctuant point, with excision of the skin edges to deroof the abscess (Figure 73.39). Pus is sent for microbiological culture (Grace) and tissue from the wall is sent for histological appraisal to exclude specific causes. With a finger in the anorectum to avoid creation of a false opening, the cavity is carefully curetted. A gentle search may be made for an underlying fistula if the surgeon is experienced, and, if obvious, a loose draining seton may be passed; injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. After irrigation of the cavity, the wound is lightly tucked; antibiotics are prescribed if there is surrounding cellulitis and especially in

Figure 73.39 Incision of an ischiorectal abscess. The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess removed by the finger wrapped in gauze. It is wise to biopsy the wall and send the pus for culture. Nothing further is done at this stage.

those less resistant to infection, such as diabetics. If the pus subsequently cultures skin-type organisms, there will be no underlying fistula and the patient can be reassured. If gut flora are cultured, it is likely, but not inevitable, that there is an underlying fistula.

The management of supralelevator sepsis is dependent upon its exact anatomy (within or outside the rectal wall) and its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn's disease, malignancy), although intrarectal drainage may be apt to avoid creation of an extrasphincteric fistula. Cephalad extension of an intersphincteric fistula can be safely drained into the rectum, whereas supralelevator extension of a trans-sphincteric fistula should be drained via the skin of the buttock. Rarely, a colostomy may be necessary to control severe sepsis, especially in the immunocompromised individual (Summary box 73.13).

Summary box 73.13

Anorectal abscess

- Usually produces a painful, throbbing swelling in the anal region. The patient often has swinging pyrexia
- Subdivided according to anatomical site into perianal, ischiorectal, submucous and pelvirectal
- Underlying conditions include *fistula-in-ano* (most common), Crohn's disease, diabetes, immunosuppression
- Treatment is drainage of pus in first instance, together with appropriate antibiotics
- Always look for a potential underlying problem

FISTULA-IN-ANO

A *fistula-in-ano*, or anal fistula, is a chronic abnormal communication, usually lined to some degree by granulation tissue, which runs outwards from the anorectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). Anal fistulae may be found in association with specific conditions, such as Crohn's disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula), and suspicion of these should be aroused if clinical findings are unusual. However, the majority are termed non-specific, idiopathic or cryptoglandular, and intersphincteric anal gland infection is deemed central to them.

Presentation

For reasons that are unknown, non-specific anal fistulae are more common in men than women. The overall incidence is about nine cases per 100 000 population per year in Western Europe, and those in their third, fourth and fifth decades of life are most commonly affected. Patients usually complain of intermittent purulent discharge (which may be bloody) and pain (which increases until temporary relief occurs when the pus discharges). There is often, but not invariably, a previous episode of acute anorectal sepsis that settled (incompletely) spontaneously or with antibiotics, or which was surgically drained. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

Caspar Bartholin, *Secundus*, 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.

William Cowper, 1666–1709, London surgeon, described these glands in 1697.

Roger Hew Grace, formerly Professor of Colorectal Surgery, The Royal Wolverhampton Hospital, Wolverhampton, UK.

Classification

The most widespread and useful classification of anal fistulae is that proposed by Parks, based on the centrality of intersphincteric anal gland sepsis (the internal opening is usually at the dentate line), which results in a primary track whose relation to the external sphincter defines the type of fistula and which influences management (Figure 73.40). Classifications based simply on level are less practical because they mean different things to different people, although the description of a fistula as high, indicating a high risk of incontinence if laid open, or low, with a lower but still some risk to function, is often used. Similarly, 'simple' and 'complex' are commonly used adjectives – complexity may be endowed by the level at which the primary track crosses the sphincters, the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Intersphincteric fistulae (45 per cent) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter, but may extend proximally in the intersphincteric plane to end blindly with or without an abscess, or enter the rectum at a second internal opening.

Trans-sphincteric fistulae (40 per cent) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and which then passes through the ischiorectal fossa to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischiorectal fossa, which may rarely pass through the levators to reach the pelvis and which may spread circumferentially (horseshoe). Circumferential spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischiorectal plane.

Suprasphincteric fistulae are very rare, are thought by some to be iatrogenic and are difficult to distinguish from high-level trans-sphincteric tracks (for which, fortunately, management strategies are similar). Extrasphincteric fistulae run without specific relation to the sphincters and usually result from pelvic disease or trauma.

Figure 73.40 Types of anal fistula (Parks' classification): 1, intersphincteric; 2, trans-sphincteric; 3, suprasphincteric; and 4, extrasphincteric primary tracks.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine are the site of the internal opening; the site of the external opening(s); the course of the primary track; the presence of secondary extensions; and the presence of other conditions complicating the fistula. Palpable induration between external opening and anal margin suggests a relatively superficial track, whereas supralelevator induration suggests a primary track above the levators or high in the roof of the ischiorectal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall's rule (Figure 73.41), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful but not infallible. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Probing in an awake patient is painful, unhelpful and can be dangerous. Full examination under anaesthesia should be repeated before surgical intervention. Dilute hydrogen peroxide, instilled via the external opening, is a very useful way of demonstrating the site of the internal opening; gentle use of probes (Figure 73.42) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

Special investigations

A successful outcome after fistula surgery requires an accurate assessment of the fistula itself, the sphincter through which it passes and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication

Figure 73.41 Goodsall's rule.

Figure 73.42 Retrograde probing of an anal canal sometimes reveals the internal orifice of the fistula.

of functional anal sphincter length, resting tone and voluntary squeeze; these may be more objectively assessed by manometry, whereas endoanal ultrasound gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. Endoanal ultrasound, especially with hydrogen peroxide, can also be used to delineate fistulae, although definition of sepsis outside or above the sphincters is limited by the probe's focal range and scarring makes interpretation difficult. Nonetheless, ultrasound, which is more accurate than clinical examination, is useful to determine whether a fistula is relatively straightforward or not. Magnetic resonance imaging (MRI) is acknowledged to be the 'gold standard' for fistula imaging, but it is limited by availability and cost and is usually reserved for difficult recurrent cases. The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and which are the cause of persistence (Figure 73.43). Fistulography and computed tomography (CT) both have limitations but are useful techniques if an extrasphincteric fistula is suspected.

Surgical management

Patients with minimal symptoms, especially if they have compromised sphincters, may be managed expectantly. Eradication of sepsis requires surgery, the aim of which must be balanced with the preservation of continence. Most fistulae are relatively straightforward to deal with; however, a minority are extremely problematic and are not the realm of the 'occasional proctologist'. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult to make because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow up and surgeon preference over-riding entry into prospective randomised trials.

Figure 73.43 Coronal magnetic resonance imaging (MRI) scan (STIR sequence) demonstrating a primary track running up the right ischioanal space (short white arrow), which then crosses the sphincters to open into the anal canal just below the puborectalis. However, there is a blind secondary extension (long white arrow) passing to the contralateral side in the roof of the left ischioanal fossa (and involving the levators), which was missed at surgery and which was the cause of fistula persistence.

Fistulotomy

That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 600 years ago. Fistulotomy, or laying open, is the surest way of getting rid of a fistula, but, by definition, it involves division of all those structures lying between the external and internal openings. It is therefore applied mainly to intersphincteric fistulae and trans-sphincteric fistulae involving less than 30 per cent of the voluntary musculature (but not anteriorly placed fistulae in women); however, even then, it is not immune to postoperative defects in continence. After full examination under anaesthesia in the lithotomy or prone jack-knife position, during which the internal opening should have been identified, a grooved fistula probe is passed from the external to the internal opening (Figure 73.44), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speeds up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair, however, are very problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

Fistulectomy

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the sphincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, then the sphincteric component can be managed by another method.

Setons

Setons (Latin: *seta*, bristle) have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about what they are trying to achieve in a particular situation. Loose setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used, but the seton should be non-absorbable, non-degenerative and comfortable. Tight or cutting setons are placed with the intention of cutting through the enclosed muscle.

John of Arderne, 1307–1390, was the first English surgeon of note. He practised at Newark-upon-Trent, Nottinghamshire and, from 1370, in London, UK. He described his operation for the treatment of fistula in about 1376.

Figure 73.44 Fistulotomy. A grooved probe is passed from the external to internal openings (a) and the track laid open over the probe (b). The track is curetted to remove granulation tissue (c), the edges of the wound are trimmed and the wound may then be marsupialised (d). Reproduced with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.

Uses of loose setons

- For long-term palliation to avoid septic and painful exacerbations by establishing effective drainage; most often in Crohn's disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence.
- Used before 'advanced' techniques (fistulectomy, advancement flap, cutting seton); acute sepsis and secondary extensions are eradicated and a loose seton is passed across the sphincteric component of the primary track to simplify the fistula and allow fibrosis.
- As part of a staged fistulotomy.
- As part of a therapeutic strategy to preserve the external sphincter in trans-sphincteric fistulae. Secondary tracks in the ischiorectal fossa are laid open. Access to the site where the primary track crosses the external sphincter may sometimes necessitate division of the anococcygeal ligaments to reach the deep post-anal space. The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate

the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. Initial postoperative management includes daily wound irrigation and light wound redressing. The seton is left in place for three months and, if there is evidence of good healing, simply removed. Such a strategy certainly protects against the consequences of external sphincter division, with an incidence of healing in the short term of 50–60 per cent.

Uses of cutting setons

Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy, but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed ('cheese wiring through ice') such that the divided muscles do not spring apart, and the site of the fistula track is replaced by a thin line of fibrosis as it is brought down. Some recommend prior

internal sphincter division, others incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and 'self-cutting' or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. In eastern parts of the world, the same aim has been achieved by chemical cautery using an Ayurvedic method, known in India as Kshara sutra, in which a specially prepared seton thread burns through the enclosed tissue. This outpatient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Advancement flaps

When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, the advancement flap technique can be employed, which aims to preserve both anatomy and function. The principles are prior elimination of acute sepsis and secondary tracks, with ideally a direct track from internal to external openings; coring out of the entire track; and closure of the communication with the anal lumen with an adequately vascularised flap consisting of mucosa and internal sphincter, sutured without tension to the anoderm, well distant from the site of the (excised) internal opening. Modifications include flap orientation (proximally or distally based) and thickness (mucosal, partial or full-thickness internal sphincter), and treatment of the external wound.

Biological agents

The functional consequences of fistulotomy and the poorer eradication rates of sphincter-preserving techniques have led to a search for agents that essentially plug and seal the track and allow ingrowth of healthy tissue to replace it (Summary box 73.14). Intuitively, success must depend on the biomaterial itself and the environment into which it is placed. The poor long-term results of fibrin glue probably result from its relatively rapid resorption, and thus inadequate time for host tissue incorporation. The variable short-term results associated with porcine small intestinal submucosa may reflect early extrusion, premature degradation within an infected field, or the protocol advocated for its use which does not include meticulous eradication of secondary extensions, or the lining of the primary track itself, whether epithelial or granulation tissue. Cross-linked porcine dermal collagen has also, more recently, been studied, but only short-term outcomes (albeit optimistic) are known. Research into biological agents must continue.

Summary box 73.14

Anorectal fistulae

- Are common and may be simple or complex
- Are classified according to their relationship to the anal sphincters
- May be associated with underlying disease, such as tuberculosis or Crohn's disease
- Laying open is the surest method of eradication, but sphincter division may result in incontinence

HIDRADENITIS SUPPURATIVA

This is a chronic suppurative condition of apocrine gland-bearing skin, which is found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the scrotum, as well as the perineum and buttocks, and is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may coexist with hidradenitis suppurativa in the condition 'follicular occlusion tetrad'.

Pathology

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection (with *Staphylococcus aureus*, *Streptococcus milleri* and anaerobes) causes further local extension, skin damage and deformity, with multiple communicating subcutaneous fistulae. There is some evidence that the disease may be related to a relative androgen excess.

Presentation

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more common in women than men, although anogenital disease is more common in men, and obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm, but it does not extend above the dentate line or involve the sphincter muscles themselves.

Differential diagnosis

In the early stages, distinction from furunculosis can be difficult. Crohn's disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

Treatment

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission, but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracts, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defunctioning colostomy to allow healing.

CONDYLOMATA ACCUMINATA (ANAL WARTS)

There is increasing evidence that sexually transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and squamous cell carcinoma of the anus. In those areas of the

world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30 years, most importantly of AIN and anal cancers. Similar virally induced changes have been noted in the genital tracts of women (vulval intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN) and cancers). There are over 80 subtypes of HPV but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy.

Condylomata acuminata is the most common sexually transmitted disease encountered by colorectal surgeons and is most frequently observed in homosexual men. Associated warts on the penis and along the female genital tract are common.

Presentation

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice. The diagnosis is aided by aceto-whitening upon application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

Treatment

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25 per cent podophyllin to discrete warts on the perianal skin is often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

ANAL INTRAEPITHELIAL NEOPLASIA

Anal intraepithelial neoplasia (Figure 73.45) is a multifocal virally induced dysplasia of the perianal or intra-anal epidermis which is associated with the human papilloma virus (most frequently subtypes 6, 11, 16 and 18). The prevalence is <1 per cent of the population with a rising incidence especially in those areas where anoreceptive intercourse and HIV are prevalent. At-risk groups include patients with HIV, as well as immunocompromised patients, women with a history of other genital intraepithelial neoplasia (VIN and CIN) and patients with extensive anogenital condylomata. Patients may be asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain, but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen's disease should probably be avoided.

Figure 73.45 Extensive anal intraepithelial neoplasia (AIN), which extends intra-anally.

Presentation

Around 10 per cent of AIN lesions are diagnosed by the pathologist after excision of abnormal skin lesions. Low-grade lesions may be raised and similar to anal condylomata; however, AIN III lesions are more often flat and may be white, grey, purple or brown in colour. Ulceration would suggest progression to invasive anal carcinoma. Patients' symptoms include pruritis, pain, bleeding and discharge. AIN is present in 28–35 per cent of excised anal warts. Approximately 10 per cent of AIN III lesions will progress to anal carcinoma at five years. Regression of AIN III rarely occurs, but AIN I and AIN II may regress. The association between AIN III and carcinoma is strengthened by the findings of AIN III in 80 per cent of anal cancer biopsies.

Diagnosis and management

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN II and III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Specialised centres may offer colposcopy of the anus (anoscopy) utilising 5 per cent acetic acid with Lugol's iodine to assess *in vivo* the dysplastic areas of the anus. The affected areas show up white and can be biopsied. Focal disease may be excised and local excision is effective for lesions <30 per cent of the circumference of the anus. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). However, for a condition with uncertain malignant potential, this approach should be used with caution as it carries with it significant morbidity. It is important to remember that female patients are at risk of other anogenital intraepithelial neoplasia; it is recommended that those with AIN III have a yearly cervical smear test.

Topical imiquimod, 5 per cent, or oral retinoids have some effect on the progression of dysplasia and can cause regression by at least two histological grades. Other newer options may include anti-human papilloma virus treatment and vaccination may reduce the incidence long term.

Abraham Buschke, 1868–1943, a German dermatologist.

LW Löwenstein described this condition in 1939.

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.

NON-MALIGNANT STRICTURES – ANAL STENOSIS

Spasmodic

An anal fissure causes spasm of the internal sphincter. Rarely, a spasmodic stricture accompanies secondary megacolon, possibly as a result of the chronic use of laxatives.

Organic

Anal stenosis is a rare but serious complication of anorectal surgery, 90 per cent are seen after haemorrhoidectomy. Other causes include trauma, inflammatory bowel disease, radiation treatment, sexually transmitted disease, tuberculosis and some skin conditions, e.g scleroderma.

Postoperative stricture

This sometimes follows a haemorrhoidectomy performed incorrectly. Removal of excess anoderm and mucosa without adequate skin bridges can lead to scarring and structuring. Stenosis can be seen after stapled haemorrhoidopexy (0.8–5 per cent) and low coloanal anastomoses, especially if a stapling gun is used, but these are really low rectal stenoses.

Irradiation stricture

This is an aftermath of irradiation and is particularly seen after chemoradiation for anal carcinoma when a wide area of skin and anoderm are irradiated. It can be seen after irradiation for any pelvic tumours.

Senile anal stenosis

A condition of chronic internal sphincter contraction is sometimes seen in the elderly. Increasing constipation is present, with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight rubber ring. There is no evidence of a fissure-in-ano. The treatment is dilatation at frequent intervals.

Lymphogranuloma inguinale

Lymphogranuloma inguinale (see Chapter 72) is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80 per cent of the sufferers are women. Frei's reaction is usually positive. This variety of rectal stricture is particularly common in black populations and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases, excision of the rectum is required.

Inflammatory bowel disease

Stricture of the anorectum may complicate Crohn's disease and, in this instance, the stricture is annular and often more than one is present. These stenoses are characterised by transmural

scarring and inflammation. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected if a stricture is found.

Endometriosis

Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

Neoplastic

When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

Clinical features

Increasing difficulty in defaecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are 'pipe-stem' in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

Rectal examination

The finger encounters a sharply defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken. Often the examination will be painful and needs to be performed under general anaesthesia when biopsies and gentle, graduated dilatation may be undertaken.

Treatment

Before starting treatment, it is important to ascertain the cause of the stricture. If associated with Crohn's disease, an anoplasty is contraindicated. Non-operative treatment is recommended for mild stenosis. The use of stool softeners and fibre supplements helps aid the passage of stools.

Prophylactic

The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of postoperative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

Dilatation

Anal dilatation can be performed under general anaesthesia and then, by the patient, using an anal dilator. For anal and many rectal strictures, dilatation at regular intervals is all that is required.

Anoplasty

For severe anal stenosis, an anoplasty is used to replace loss of anal tissue. The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect

Wilhelm Sigmund Frei, 1885–1943, Professor of Dermatology, the State Hospital, Spandau, Berlin, who later settled in New York, NY, USA, described his test for lymphogranuloma inguinale in 1925.

George Grey Turner, 1877–1951, Professor of Surgery, The University of Durham (1927–1934) and at The Royal Postgraduate Medical School, Hammersmith Hospital, London, UK (1935–1946). The surgical club Grey Turner Surgical Club was named after him. It is said that he dressed shabbily so that when his friends met him they used to ask him to 'mend the clock'. He had a habit of keeping his cup of tea warm by covering it with his bowler hat!

and enlarges the anal orifice (Figure 73.46). This technique is particularly useful for postoperative strictures.

Colostomy

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-in-ano. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

Rectal excision and coloanal anastomosis

When the strictures are at or just above the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis with good functional results (Summary box 73.15).

Summary box 73.15

Benign anal stricture

- May be spasmodic or organic
- May be iatrogenic, e.g. after haemorrhoidectomy or repair of imperforate anus
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation
- Severe anal stenosis may require an anoplasty

MALIGNANT TUMOURS

Malignant lesions of the anus and anal canal

Anal malignancy is rare and accounts for less than 2 per cent of all large bowel cancers. The crude incidence rate is 0.65 per 100 000. Those arising below the dentate line are usually squamous, whereas those above are variously termed basaloid, cloacogenic or transitional. Collectively, they are known as epidermoid carcinomas, and management and prognosis is similar for this group, which accounts for >70 per cent of anal malignancies. Adenocarcinomas are the next most common. Other tumours include melanoma, lymphoma and sarcoma.

Squamous cell carcinoma

Although rare, the incidence of anal squamous cell carcinoma (SCC) is rising, with a direct association with HPV infection,

AIN and immunosuppression. Anal SCC is associated with HPV (especially subtypes 16, 18, 31 or 33) in 70–90 per cent of cases (Figure 73.47). Patients at increased risk are those with HIV infection, recipients of organ transplants (renal transplant patients have a 100-fold increased risk) and those with a past history of cancers at 'sexually accessible' sites (usually genital). Pain and bleeding are the most common symptoms and the disease is thus often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers. There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident.

Management

Historically, early anal margin tumours were treated by local excision and anal canal tumours by abdominoperineal excision of the rectum. Nowadays, primary treatment is by chemoradiotherapy (combined modality therapy (CMT)) (Nigro), the chemotherapy usually including a combination of 5-fluorouracil (5-FU) with mitomycin C or cisplatin. Metastases are rare at presentation (5 per cent) and treatment is aimed at local control. Initial staging involves a clinical examination and biopsy of the primary tumour, as well as examination of inguinal nodes. Local staging is by MRI scanning and CT is used to assess lungs and abdomen for metastatic spread. Positron emission tomography (PET) CT may help in equivocal inguinal node assessment. The surgeon has an important role in management: initial diagnosis is surgical; small marginal tumours are still best treated by local excision; radical surgery is indicated in those with persistent or recurrent disease following CMT; and a defunctioning stoma may be indicated for those in whom treatment and disease regression is associated with radionecrosis, incontinence or fistula. Despite good results with chemoradiotherapy 20–25 per cent of patients will have local disease relapse. After thorough assessment, these patients may require radical abdominoperineal resection, including excision of the posterior wall of the vagina in 70 per cent of women and reconstruction of the perineum using myocutaneous flaps.

Other anal malignancies

Adenocarcinoma within the anal canal are usually extensions of distal rectal cancers. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a longstanding

Figure 73.46 (a–c) Y-V advancement flap for anal stenosis.

Figure 73.47 Neglected papillomas of the anus that have become malignant.

(usually complex) anal fistula; treatment is as for low rectal cancers (i.e. abdominoperineal excision of the rectum (APER) with or without previous radiotherapy or chemoradiotherapy), but prognosis is less good. Melanocytes can be found in the transitional zone of the anal canal. Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external pile, although it may be amelanotic (Figure 73.48). The prognosis, irrespective of treatment, is extremely poor. Perianal Paget's disease is exceedingly rare (Summary box 73.16).

Summary box 73.16

Anal cancer

- Uncommon tumour, which is usually a squamous cell carcinoma
- Associated with human papilloma virus (HPV)
- More prevalent in patients with HIV infection
- May affect the anal verge or anal canal
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required if the above fails

Figure 73.48 Malignant melanoma of the anal canal (courtesy of Mr B Thomas, Kalushi, Zambia).

LEARNING OBJECTIVES

To recognise and understand:

- The major symptoms of urological disease

- The most common urological investigations

URINARY SYMPTOMS

Haematuria

Blood in the urine (haematuria) may be the only indication of cancer and other pathology in the urinary tract (Figure 74.1). Microscopic haematuria may be detected by dipstick testing in a routine health check. A substantial haemorrhage imparts a red or brownish tinge to the urine (macroscopic haematuria) and the patient may pass clots. False-positive stick tests and the discoloured urine caused by beetroot and some drugs (e.g. Dindevan (phenindione), Pyridium (phenazopyridine) and Furadantin (nitrofurantoin)) are distinguishable by the absence of red blood cells on urinary microscopy.

Haematuria may be intermittent or persistent. If the patient experiences pain with haematuria, the characteristics of the pain may help to identify the source of the bleeding. If there is a malignant cause for the haematuria, there is usually no pain.

In practice, all patients with haematuria should be investigated even if they are taking anticoagulant drugs. In many, all tests will be negative: the chance of finding a urological cause in patients under 40 years of age with microscopic haematuria is small. However, bleeding into the urinary tract may be caused by an occult nephropathy so it is important to check for significant proteinuria and hypertension in these patients (Summary box 74.1).

Pain

Renal pain

A deep-seated, sickening ache in the loin characterises acute upper urinary tract inflammation or obstruction, probably as the result of stretching of the capsule of the kidney. Even small and peripheral kidney stones may cause pain, even in the absence of infection. Large slow-growing masses such as tumours or cysts

Figure 74.1 The more common causes of haematuria.

Summary box 74.1

Haematuria

- Is always abnormal whether microscopic or macroscopic
- May be caused by a lesion anywhere in the urinary tract
- Is investigated by:
 - examination of midstream specimen for infection
 - cytological examination of a urine specimen
 - intravenous urogram and/or urinary tract ultrasound scan
 - flexible or rigid cystoscopy
- Is commonly caused by urinary infection, especially in young women

Summary box 74.2**Pain from the upper urinary tract**

- Pain of acute obstruction of the renal pelvis is typically deep in the loin and 'bursting' in character
- Ureteric colic (usually due to stone) is characterised by sharp exacerbations against a constant background
- Pain is referred to the groin, scrotum or labium as calculus obstruction moves distally in the ureter

Summary box 74.3**Pain from the lower urinary tract**

- Is commonly felt as suprapubic discomfort, worsening as the bladder fills
- Cystitis causes burning or scalding urethral pain (dysuria)
- May be referred to the tip of the penis in men, even when lesion is in the bladder

are commonly painless. When the cause is inflammatory, there may be local deep tenderness and occasionally reflex spasm of the psoas muscle and involuntary flexion of the hip joint.

Ureteric colic

This is an acute pain felt in the loin and radiating to the ipsilateral iliac fossa and genitalia. The patient often rolls around in agony as waves of excruciating pain are imposed upon a continuing background of discomfort. Contrast this with the patient suffering from peritoneal pain, who lies still because movement hurts.

Blood clot or a sloughed renal papilla may give identical pain. The site of the pain is a partial guide to the progress of a stone: the more the pain radiates into the groin, the more distal the stone. Local tenderness is much less than would be expected from the severity of the pain (Summary box 74.2).

Bladder pain

Bladder pain is a suprapubic discomfort worsened by bladder filling. In men, a sharp pain misleadingly referred to the tip of the penis may be the result of irritation of the bladder trigone. Severe inflammation of the bladder can cause strangury, an extreme wrenching discomfort at the end of micturition.

Perineal pain

This is experienced as a penetrating ache in the perineum and rectum, sometimes with associated inguinal discomfort. The patient is characteristically depressed by the relentless pain. Pelvic pain is often blamed on 'chronic prostatitis', 'prostadynia' or 'chronic prostate pain syndrome', but it occurs in both men and women. It is notoriously difficult to treat, a characteristic shared with various chronic scrotal pain syndromes.

Urethral pain

Urethral pain is a scalding or burning felt in the vulva or penis, especially during voiding (Summary box 74.3).

Altered bladder function

The normal bladder has two phases of function. During the fill-

ing phase, the bladder acts as a reservoir to collect urine until it is emptied in the voiding phase. Inappropriate contraction of the bladder detrusor muscle during filling (instability) is perceived as a sensation of urgency. There may be frequent micturition with or without urge incontinence. Sleep may be disturbed by nocturia. Instability may be idiopathic in both sexes or part of the bladder response to outflow obstruction, notably in prostatic disease. When detrusor instability has a demonstrable neurological cause, it is known as hyperreflexia.

Symptoms of impaired emptying are most commonly the result of bladder outflow obstruction, but detrusor failure presents a similar picture. The patient has difficulty initiating voiding (hesitancy) and the stream is variable or slow. Abdominal straining improves the weak flow. When micturition is complete, the bladder may still feel full. With time, the bladder becomes chronically overfilled. Urine spills out, typically at night when sleep halts trips to the lavatory (chronic retention with overflow) (Summary box 74.4).

Summary box 74.4**Altered bladder function**

- Failure bladder storage function leads to urgency and frequency of micturition, often by day and by night
- Failure of bladder emptying function is most commonly caused by obstruction to the bladder outflow (e.g. by prostatic enlargement) but can also be caused by weakness of the detrusor muscle
- Chronic retention of urine may present as nocturnal bedwetting

INVESTIGATION OF THE URINARY TRACT

With the exception of renal and scrotal masses or tenderness, a palpable bladder or an abnormal prostate on digital rectal examination, urological conditions are most likely to be diagnosed from the history or by investigations.

Urine

Dipsticks (Multistix, Labstix) are a convenient way to screen urine for blood, protein or nitrites. When the urine is macroscopically clear and negative on dipstick testing, microscopy and culture of a midstream clean-catch specimen are usually negative. The presence of protein and nitrites (produced by organisms in the urine) indicates the likelihood of infection. The significance of microscopic haematuria is discussed above. Some dipsticks also give an indication of the pH and specific gravity of the urine.

Microscopy confirms the presence of white and red blood cells in the urine, and bacteria may also be visible. Protein casts suggest disease of the renal parenchyma, as does red cell dysmorphism seen on phase contrast microscopy. Schistosoma ova have a typical appearance (Figure 74.2), and vegetable or meat fibres may be present if there is a fistula connecting the bowel with the urinary tract.

Cytological examination of the urinary sediment is sensitive and specific for poorly differentiated transitional cell tumours anywhere in the urinary tract. However, false negatives are common when the cancer is well differentiated. A chemical test

Figure 74.2 Schistosoma ovum (courtesy of Dr Nawal Derius).

(BTA-Bard) for bladder tumour antigen in the urine can complement cytological examination.

Bacteriological culture of a clean-catch midstream specimen of the urine is the standard means of identifying urinary pathogens. Organisms at a level of $>10^5$ /mL is deemed to indicate the presence of infection rather than contamination of the urine by bacteria. If there are pus cells in the urine but there is no growth on the routine culture media (sterile pyuria), it is worth testing for more fastidious organisms. The centrifuged sediment of multiple early-morning urine specimens are cultured on Löwenstein–Jensen medium to detect urinary tract tuberculosis. Chlamydia is another common urinary pathogen that will not be detected on routine culture.

Biochemical examination for electrolytes, glucose, bilirubin, haemoglobin and myoglobin is essential to detect abnormal amounts of these substances in the urine. Analysis of a 24-hour specimen of urine will quantify the rate of loss, and is especially useful in the investigation of calculus disease caused by abnormal excretion of calcium, oxalate, uric acid and other products of metabolism (Summary box 74.5).

Summary box 74.5

Microscopic, cytological, bacteriological and biochemical examination of urine

- Abnormalities found on Multistix testing of the urine should be confirmed by microscopy and culture
- More than 10^5 organisms per mL of urine is deemed to indicate a significant urinary infection
- Cytological examination of the urine will usually detect a poorly differentiated transitional cell tumour

Tests of renal function

More than 70 per cent of kidney function must be lost before renal failure becomes evident: there is a large functional reserve. It follows that renal damage must be extensive before changes occur in blood constituents whose level is controlled by renal excretion. Such damage is of three main types: reduction of renal plasma flow, destruction of glomeruli and impairment of tubular function. In severe hypertension or renal artery stenosis, the plasma flow is impaired. In glomerulonephritis or acute

cortical necrosis, there is a loss of glomeruli, whereas in pyelonephritis, tubular function is most severely affected. In obstructive nephropathy, back pressure on the renal parenchyma causes all three types of damage.

Levels of blood urea and serum creatinine can be affected by various factors but, when taken together they serve as a useful clinical guide to overall renal function. A creatinine clearance test will give an approximate value for glomerular filtration rate but is prone to error. A more accurate assessment of glomerular function can be obtained from an estimate of the clearance of chromium-51-labelled ethylenediaminetetraacetic acid. Surgeons will usually call on their nephrological colleagues for more detailed investigations of tubular function and renal blood flow.

The specific gravity of the urine is fixed at a low level when the kidney loses the power to concentrate because of renal tubular dysfunction. Estimation of the urinary loss of sodium, β_2 -microglobulin or the tubular enzyme *N*-acetylglucosamine (NAG) will further define the nature of any functional impairment (Summary box 74.6).

Summary box 74.6

Tests of renal function

- Elevated blood urea and serum creatinine levels usually indicate a significant impairment of renal function
- More sophisticated renal assessment is required to quantify the functional deficit

Imaging

A plain abdominal x-ray showing the kidneys, ureters and bladder (the KUB) is a simple and useful test. Abnormalities of the spine and other bony structures including scoliosis, spina bifida, degenerative disease of the spine, metastases, fractures and arthritis may be relevant to the urological diagnosis. The soft-tissue renal shadows, outlined by their more radiolucent fatty coverings, overlie the upper attachments of the psoas muscles. A full bladder often presents a hazy outline arising from the pelvis.

Most urinary calculi absorb x-rays and lie in the region of the renal shadows and along the course of each ureter. These normally follow the tips of the transverse processes of the vertebrae, cross the sacroiliac joints and head for the ischial spine before hooking medially towards the bladder base. Stones with a low calcium content and those overlying bony structures may be difficult to see on the plain film. Pelvic phleboliths are very common and can look like lower ureteric calculi. Uric acid stones are the most common radiolucent calculi (Summary box 74.7).

Summary box 74.7

Straight abdominal radiograph

- Most urinary calculi are radiodense
- Uric acid calculi are typically radiolucent

Intravenous urography (urography)

Excretion renography has been a mainstay of urological investigation since the introduction of intravenous contrast media in the 1930s. These are organic chemicals to which iodine atoms are attached to absorb x-rays. When such a chemical is injected intravenously, it is filtered from the blood by the glomeruli and does not undergo tubular absorption. As a result, it rapidly passes through the renal parenchyma into the urine, which it renders radio-opaque.

Although intravenous urography (IVU) gives excellent images of the urinary tract (Figure 74.3), its use should be restricted because in a few patients the iodine in the contrast medium may cause an anaphylactic reaction. Patients with a history of allergy, atopy and eczema are particularly vulnerable, but severe reactions may occur without warning. Less invasive and dangerous imaging techniques are clearly to be preferred if they are able to give comparable diagnostic information (Summary box 74.8).

Summary box 74.8

Intravenous urography

- IVU can cause a dangerous hypersensitivity reaction in a small number of patients

Preparation

A laxative will clear faeces that might otherwise obscure details of urinary tract anatomy. Modest fluid restriction is permissible, but dehydration is dangerous because it may precipitate acute renal failure.

Technique

The patient is observed carefully while the first few drops of contrast medium (Urografin or Niopam 370) are injected. The earliest films show the renal parenchyma opacified by contrast medium – the nephrogram phase. A delayed nephrogram on one side indicates unilateral functional impairment. Distortion of the renal outline or failure of part of the kidney to function suggests a space-occupying lesion.

Figure 74.3 Normal intravenous urogram showing the outline of both kidneys with the collecting system and upper ureters highlighted by the contrast medium.

After a few minutes, the contrast is excreted into the collecting system, opacifying the calyces and the renal pelvis. Later films show the ureters and, at the end of the study, the patient is asked to pass urine and a final film is taken to show details of the bladder area. It is important to bear in mind that the static images of IVU provide only snapshots of dynamic events in the urinary tract. The appearance of a normal ureter changes as peristaltic waves of contraction pass along it.

IVU is particularly valuable to demonstrate tumours and calculi within the urinary tract, which are sometimes difficult to see on ultrasonography. It may also be useful to show details of abnormal anatomy that are difficult to interpret on an ultrasonogram.

As ultrasonography and other forms of scanning have become more sophisticated, the indications for the urogram are fewer and it may eventually fall into disuse. Obstruction to the upper urinary tract interferes with transport of contrast medium into the urine, which will show up as a non-functioning kidney on the standard urogram films. In these circumstances, a further x-ray taken many hours after injection of the contrast medium may show hazy opacification of a dilated system. Distortion of the calyces or the renal outline can equally be caused by a tumour or by harmless simple cysts. In each of these cases, more information can be obtained from ultrasonography or computed tomography (CT).

Retrograde ureteropyelography (synonym: retrograde ureterogram)

A ureteric catheter is passed into the ureteric orifice through a cystoscope (Figure 74.4). Contrast medium injected through the catheter will demonstrate the anatomy of the upper urinary tract. This is particularly useful if there is doubt about an intraluminal lesion (Figure 74.5) or if renal function is deficient (before surgery for pelviureteric junction obstruction, for instance). When a transitional tumour is found, it can be sampled by aspiration of urine from the upper tract or by brush biopsy. Retrograde ureteropyelography is possible under topical urethral anaesthesia using a flexible cystoscope. Introducing infection into a poorly draining part of the system carries a serious risk of septicaemia. If there is to be any delay in correcting the blockage surgically, facilities must be available to decompress the kidney by retrograde stenting or percutaneous nephrostomy.

Figure 74.4 A ureteric catheter about to enter the left ureteric orifice. Cystoscopic view.

Figure 74.5 Retrograde ureterogram demonstrating the collecting system. The radiolucent filling defect in the renal pelvis is caused by a uric acid calculus.

Antegrade pyelography

Percutaneous puncture of a dilated renal collecting system is reasonably simple. The most common indication is the placement of a nephrostomy tube to drain an obstructed infected kidney or to provide access for percutaneous nephrolithotomy. Antegrade pyelography – in which contrast medium is introduced through the nephrostomy – can be helpful when retrograde studies are prevented by obstruction at the extreme lower end of the ureter.

Digital subtraction arteriography

Refinements in radiological imaging have now almost eliminated the need for translumbar aortography. Satisfactory imaging of the renal vessels can be achieved by digital subtraction angiography after intravenous injection of contrast medium. More precise information can be obtained by intra-arterial injection through a fine catheter inserted into the femoral artery using the Seldinger technique. Arteriography is now rarely used to demonstrate tumour vasculature in a hypernephroma (Figure 74.6), but a flush venogram is useful when CT suggests tumour invasion of the renal vein and vena cava.

Cystography

Cystography is now most commonly a component of video-urodynamic assessment (see Chapter 76). Its role in assessing ureteric reflux in children has been largely superseded by radioisotope scanning and dynamic ultrasonography.

Figure 74.6 A selective renal arteriogram showing abnormal vessels in a renal cell carcinoma.

Urethrography

Ascending urethrography is valuable to demonstrate the extent of a urethral stricture (Figure 74.7) and the presence of false passages and diverticula associated with it. A urethrogram can be used to assess the extent of urethral trauma, but there is a serious danger that contrast medium may pass into the circulation. Lipiodol carries the danger of fat embolus and should never be used, and death has followed the use of barium emulsion. Umbradil viscous V is a radio-opaque water-soluble gel that contains the local anaesthetic lignocaine. It can be injected gently and safely using Knutsson's apparatus even if the urothelium is breached.

Venography

Extension of a renal carcinoma from the renal vein into the vena cava can usually be demonstrated by ultrasound or CT, but venography was used for this purpose.

Ultrasonography

Ultrasonography is perhaps the imaging technique most widely used in urology. Kidney size, the thickness of its cortex and the presence and degree of hydronephrosis can be measured with great accuracy. Intrarenal masses can be diagnosed as smooth walled and fluid filled (simple cysts) or solid and complex (possible tumours). Stones produce a bright ultrasonic reflection and cast an acoustic shadow (Figure 74.8). The volume of urine in the bladder before and after micturition can be calculated, and even tiny filling defects within it detected. Scrotal contents can be displayed in great detail. The prostate is accessible by the transrectal route. Only the lower ureter resists effective investigation by transabdominal ultrasonography because of its small calibre and its proximity to the large bones of the pelvis and spine (Summary box 74.9).

Figure 74.7 Ascending urethrogram demonstrating a tight stricture in the bulbar urethra. Above the stricture the contrast outlines the prostatic urethra and bladder.

Summary box 74.9

Ultrasonography

- Ultrasound scanning provides broadly similar anatomical information to an intravenous urogram but without the risks

Transrectal ultrasonography

This has become a routine component of the investigation of suspected carcinoma of the prostate. Most commonly, suspicion has arisen because the level of prostate-specific antigen is raised or there is an abnormality of the texture or outline of the prostate on digital rectal examination. The features of carcinoma or benign enlargement of the prostate, although not absolutely specific, are sufficiently well recognised to allow an experienced ultrasonographer to identify promising sites for transrectal fineneedle biopsy.

Computed tomography

CT is particularly useful to assess structures in the retroperitoneum (Figure 74.9). In renal carcinoma it will show:

- the size and site of the tumour and the degree of invasion of adjacent tissue;
- the presence of enlarged lymph nodes at the renal hilum;
- invasion of the renal vein and vena cava.

CT is of crucial importance in the initial staging and follow up of men with testicular cancer, in whom the presence of retroperitoneal lymph node masses features in advanced disease. It has also been used to stage bladder and prostate cancer, but its value is less clearcut in these diseases. Non-contrast CT is also

Figure 74.8 A calculus in the kidney casts an acoustic shadow (courtesy of Dr Matthew Matson).

used routinely in the diagnosis of urinary calculi (Figures 74.10 and 74.11).

Magnetic resonance imaging and positron emission tomography

These technologies give information about the function of organs as well as detailed structural images. As they become more widely available, they are replacing many of the routine imaging techniques.

Radioisotope scanning

Radioisotope scanning is used to obtain information about function in individual renal units. Diethyltriamepentaacetic acid (DTPA) behaves in the kidney like inulin: it is filtered by the glomeruli and not absorbed by the tubules. Using a gamma camera, DTPA labelled with technetium-99m can be followed during its transit through individual kidneys to give a dynamic representation of renal function. A ^{99m}Tc -DTPA scan is particularly useful to prove that collecting system dilatation is caused by obstruction. In obstruction, radioactivity will remain in the kidney even if urine flow is stimulated by administra-

Figure 74.9 Computed tomography showing renal cell carcinoma of the right kidney.

Figure 74.10 A non-contrast computed tomography scan clearly shows a calculus in the left upper ureter (courtesy of Dr Matthew Matson).

tion of a diuretic like frusemide (furosemide). Other substances (dimercaptosuccinic acid (DMSA), mercaptoacetylglycine (MAG-3) and sodium orthoiodohippurate (Hippuran)) labelled with suitable radioactive isotopes have similarly been used to investigate renal function (Figure 74.12).

Isotope bone scanning is fundamental to the staging of kidney and prostate cancers, which typically metastasise to the skeleton.

Endoscopy

Visual inspection of the lower urinary tract has been possible since 1877, when Nitze invented his cystoscope. A leap forward in urological endoscopy came with the introduction by Hopkins of the rod lens telescope and fiberoptic illumination. This allowed development of a family of endoscopes, which allow the urologist to visualise the upper and lower urinary tracts for diagnosis and therapy. Finally, in the early 1980s, the small calibre flexible fibroscopic cystoscope was introduced. This allows simple diagnostic cystourethroscopy, bladder biopsy and retrograde ureterography to be performed under topical urethral anaesthesia with minimal discomfort to the patient (Summary box 74.10).

Summary box 74.10

Diagnostic examination

- Diagnostic examination of the bladder is performed painlessly under local anaesthesia using a flexible cystoscope

ANURIA

Anuria is defined as the complete absence of urine production. Oliguria is present when less than 300 mL of urine is excreted in a day (Summary box 74.11).

Summary box 74.11

Diagnosing anuria

- Check that the bladder is empty before diagnosing anuria
- Ultrasound the bladder

The maintenance of renal function and urine production depends upon perfusion of the kidneys with oxygenated blood. Reduced renal blood flow or hypoxia impairs renal function. When both are present, the danger of acute renal failure is even greater.

Renal failure is traditionally divided into:

- prerenal;
- renal;
- postrenal (obstructive).

Prerenal

Prerenal causes of acute renal failure include:

- hypovolaemia;
- blood loss;
- sepsis;
- cardiogenic shock;
- anaesthesia;
- hypoxia.

Hypovolaemia

This may result from inadequate fluid intake or from excessive loss of body water. Dehydration, prolonged vomiting, diarrhoea and other abnormal gastrointestinal fluid losses, burns and excessive sweating are all common causes of hypovolaemia.

Blood loss

This is usually caused by trauma or surgery, but acute blood loss from the gastrointestinal tract or haemorrhage associated with childbirth may be sufficient to cause hypovolaemic renal impairment.

Sepsis

Gram-negative septicaemia from a urinary tract source is a particularly potent cause of bacteraemic shock. Sepsis from the biliary tract and overwhelming infection from other sites, especially in the immunocompromised individual, are also associated with acute renal failure.

Cardiogenic shock

Acute dysrhythmia secondary to myocardial infarction, cardiac tamponade and pulmonary embolus may all result in reduced cardiac output of often poorly oxygenated blood.

Anaesthesia

Hypotension is a hazard of epidural and spinal anaesthesia.

Hypoxia

Prolonged hypoxia from any cause may occasionally be responsible.

Bozzini, at Frankfurt in 1806, devised the first cystoscope. However, **Nitze**, a urologist from Berlin, in 1877 is credited to have been the first to demonstrate the use of the cystoscope helped in some way by **Beneche**, a Viennese optician.

Figure 74.11 Reconstructed spiral computed tomography scan showing calculi in the right kidney (courtesy of Professor R Resnek).

Renal

Renal causes of acute renal failure include:

- drugs;
- poisons;
- contrast media;
- eclampsia;
- myoglobinuria;
- incompatible blood transfusion;
- disseminated intravascular coagulation.

Drugs

Aminoglycosides, cephalosporins and diuretics can be nephrotoxic, particularly if used in combination. They are quite commonly used in patients whose renal function is already compromised by sepsis or circulatory abnormalities. Prolonged use of non-steroidal anti-inflammatory drugs (NSAIDs) can cause a chronic interstitial nephritis and papillary necrosis; they also reduce renal plasma flow and therefore have nephrotoxic properties. Angiotensin-converting enzyme inhibitors used for the control of hypertension can cause a rapid reduction in the

Figure 74.12 Radioisotope renogram.

glomerular filtration rate; this is particularly liable to occur in patients who have a reduced renal blood flow.

Poisons

Some of these are nephrotoxic.

Contrast media

Even modern contrast media may cause renal failure when injected into a dehydrated patient with compromised renal function.

Eclampsia

The early recognition of pre-eclampsia is vital to avoid the nephrotoxic consequences of toxæmia and uncontrolled hypertension.

Myoglobinuria

The presence of myoglobin in the urine is associated with the 'crush' syndrome after major trauma. Less severe injuries can also cause the syndrome, especially if a compartment syndrome is unrecognised or pressure areas break down.

Incompatible blood transfusion

This may lead to renal failure with myoglobinuria.

Disseminated intravascular coagulation

Disseminated intravascular coagulation usually follows major sepsis or massive blood transfusion and may occur post-partum.

Obstructive

Obstructive causes of acute renal failure include:

- calculi;
- pelvic malignancy;
- surgery;
- retroperitoneal fibrosis;
- bilharzia;
- crystalluria.

Calculi

Renal calculus disease is probably the most common cause of acute obstruction leading to anuria. The patient is likely to have unilateral renal colic against a background of non-function of the contralateral kidney, often due to previous surgery or pre-existing obstruction by calculus.

Pelvic malignancy

Carcinomas arising from the bladder, prostate, cervix, ovary or rectum can all lead to obstruction of one or both ureters. A history of haematuria and vaginal or rectal bleeding signpost the diagnosis. A large pelvic mass is commonly palpable on bimanual examination.

Surgery

The ureters are vulnerable to damage during pelvic and retroperitoneal surgery, but injury should be avoided if proper care is taken. It is unusual, but not impossible, to damage both ureters.

Retroperitoneal fibrosis

For details of retroperitoneal fibrosis, see Chapter 75.

Bilharzia

Schistosomiasis may lead to ureteric fibrosis and stenosis, and may be responsible for the development of squamous cell carcinoma of the bladder.

Crystalluria

Uric acid crystalluria can develop in patients receiving chemotherapy for leukaemia or lymphoma unless they are given prophylactic treatment with allopurinol.

Clinical aspects

Answers to the following questions should indicate the probable cause of reduced urine output.

- **Is urine being produced?** Bladder catheterisation is essential if a voided sample cannot be obtained. If urine is available, check the specific gravity, look for the presence of casts (implying a renal cause), test for myoglobinuria and send a sample for culture and microscopy.
- **Is there an obvious prerenal cause?** This can usually be answered by clinical examination, assessment of the patient's vital signs, examination of the fluid balance chart and measurement of the arterial oxygen concentration.
- **Is there ureteric obstruction?** Hydronephrosis may not be marked in acute obstruction, but ultrasonography will usually show some degree of ureteric dilatation. A plain abdominal x-ray should be checked for calculi.
- **What drugs have been given recently?** If a drug is thought to be responsible for renal impairment, it should obviously be withdrawn unless its use is vital.
- **Is this a progression to chronic renal failure?** The presence of shrunken kidneys on ultrasound, normochromic anaemia and hypertension suggest progression to a chronic state even if a previous history of renal failure is not available.

Management and treatment

Renal failure caused by acute tubular necrosis may progress through three recognisable phases:

- 1 oliguria;
- 2 the diuretic phase;
- 3 recovery.

The initial management is aimed at prompt restoration of the circulating volume deficit and correction of tissue hypoxia. Most patients will require a level of care that is available only in a specialised unit. As a minimum, monitoring with a pulse

oximeter and central venous pressure measurements will supplement basic observations. For patients with hypovolaemia or sepsis, inotropic support with dopamine may improve cardiac efficiency and increase renal blood flow. If urine production is not promptly restored, frusemide (furosemide) can be given, but this is not always successful and the drug itself may be nephrotoxic. Mannitol may be used as a plasma expander and osmotic diuretic, but care must be taken not to overload the circulation. The aim is to achieve the best possible blood pressure, with a central venous pressure of 7–9 cmH₂O. It may be that 100 per cent oxygen is needed to maintain the oxygen tension (PO₂).

If these measures fail, acute tubular necrosis has supervened. Excess fluid loads must be avoided and fluid input restricted to match the reduced output plus insensible losses (500–800 mL per 24 hours depending on ambient conditions). Abnormal losses due to vomiting, nasogastric aspiration, diarrhoea or fistulae should be monitored and replaced.

A hyperkalaemic acidosis is the characteristic metabolic abnormality of the oliguric phase of renal failure. Correction of the metabolic acidosis with intravenous bicarbonate is tempting but not always advisable. Rising serum potassium is life-threatening and requires effective intervention. A calcium resonium enema is the simplest remedy. The ion-exchange resin can also be administered orally but is unpalatable. Cautious use of intravenous dextrose and insulin should be considered if ion exchange fails. The help of a renal physician is highly desirable because urgent dialysis may become necessary to save life (Summary box 74.12).

Summary box 74.12

Shared management with nephrologist

- Enlist the help of a nephrologist at an early stage in the management of renal failure

The diuretic phase traditionally occurs between the eighth and tenth day but may be delayed as long as 6 weeks. Glomerular filtration recommences but tubular function takes longer to recover. A heavy loss of sodium and potassium can be expected, and fluid and electrolyte requirements must be carefully judged. In most patients the diuretic phase is followed by the recovery phase, but some never recover and will need renal replacement therapy if they are to survive.

Factors that influence the outcome of acute renal failure include the need for artificial ventilation, the need for inotropic support and the presence of jaundice. There is a significant mortality rate.

Nutritional support

Many patients are unable to eat. If enteral feeding is impossible, parenteral nutrition must be administered, with extreme care to avoid circulatory overload.

Infection

These patients are at increased risk of generalised infection. Swabs taken from the nose and throat, sputum specimens and urine, if available, should be sent for culture. If antibiotics are required, they should be non-nephrotoxic.

General nursing care

Meticulous recording of fluid balance is obviously central to the successful management of these patients. Patients who are seriously ill or comatose need regular turning and care of pressure areas if they are to avoid pressure sores. Physiotherapy to the chest and extremities will aid recovery.

Renal support

Renal replacement is needed for those patients in whom the oliguric or anuric phase is associated with significant uraemic symptoms (vomiting, muscular twitching, itching and altered states of consciousness) or uncontrollable hyperkalaemia (Summary box 74.13).

Summary box 74.13

Life-threatening hyperkalaemia

- In acute renal failure, significant hyperkalaemia is life-threatening and should be corrected at an early stage

Peritoneal dialysis

Provided that the patient has not had recent abdominal surgery, peritoneal dialysis can be performed by insertion of a fenestrated catheter under local anaesthetic. This is placed just inferior to the umbilicus in the midline. Sterile dialysis fluid is then run into the peritoneal cavity, where it equilibrates with the extracellular fluid using the peritoneum as a dialysis membrane. After a variable time, the fluid is drained into a closed drainage system. The process is repeated in cycles. Occasionally, when anuria is prolonged, a cuffed catheter needs to be inserted, as used in chronic ambulatory peritoneal dialysis. The disadvantages of acute peritoneal dialysis are the potential for introducing infection into the peritoneum and the rather slow rate of correcting metabolic imbalance, particularly hyperkalaemia.

Haemodialysis

A few sessions of haemodialysis may be life-saving. A double lumen catheter is placed over a guidewire into one of the great veins (jugular, subclavian or femoral). Between sessions of dialysis the lines are kept patent by filling them with heparin solution. Haemodialysis can result in a rapid correction of metabolic abnormalities, but also tends to result in considerable fluctuations of the overall fluid balance. The other disadvantage is that heparinisation is necessary, and this may be undesirable after a recent surgical procedure.

Haemofiltration

This, like haemodialysis, requires the use of an extracorporeal machine but causes much less haemodynamic upset. This may be of critical importance for the acutely ill patient.

Obstructive renal failure

When the patient is too ill for surgery to remove the cause of obstruction to the upper urinary tract, the treatment of obstructive renal impairment is drainage, either externally using a nephrostomy or internally using an indwelling stent (Summary box 74.14).

Summary box 74.14**Catheterisation and stents**

- Urethral or suprapubic catheterisation will relieve obstruction distal to the bladder
- Indwelling stents to relieve ureteric obstruction can be inserted cystoscopically or percutaneously

Percutaneous nephrostomy

Under ultrasonographic guidance and local anaesthetic, a fine bore hollow needle is introduced via the flank through the parenchyma and into the expanded collecting system of the obstructed kidney. Once it penetrates the system, contrast medium can be injected through the needle to define its exact position. A wire passed through the lumen of the needle is used to guide the insertion of a series of dilators, which enlarge the track until it will accept a suitably sized nephrostomy tube (Figure 74.13). This will drain urine and pus, provided that the latter is not too viscous. The tube is anchored firmly in place to allow continued drainage as renal function recovers.

Insertion of a J-stent

The ureter can be drained into the bladder by the insertion of a pigtail- or J-stent (see Figure 74.13). The procedure begins with a retrograde ureterogram under fluoroscopic control to provide an image of the ureter. This will often give an indication of the cause of the obstruction. A guidewire is introduced through the ureteric orifice and guided up the ureter into the renal pelvis. The stent is rail-roaded over the guidewire until its distal end also lies within the renal pelvis above the obstruction. When the guidewire is removed, the ends of the stent curl to form a J-shape or a pigtail to secure the device against migration. Stents can be placed under topical urethral anaesthesia using the flexible cystoscope and may be safely left in position for several months. As a foreign body in the urinary tract, stents are prone to infection and encrustation if neglected. It is vital to keep careful records to account for all stents inserted.

If the J-stent cannot be inserted cystoscopically, it may be placed from above through a nephrostomy.

Open surgery

This is a rarity when the minimally invasive methods described above are available. Retrograde insertion of a nephrostomy through an incision in the renal pelvis is the preferred method because it can be surprisingly difficult to locate even dilated calyces by blind puncture of the renal parenchyma.

Figure 74.13 X-ray showing a left-sided, pigtail nephrostomy tube draining a kidney obstruction by a ureteric calculus, seen at the level of L3–4. A J-stent is in the right ureter, which has been cleared of stones.

LEARNING OBJECTIVES

To recognise and understand:

- Important congenital abnormalities of the upper urinary tract
- Important cystic diseases of the kidney
- The management of open and closed trauma to the kidney and ureter
- The aetiology, presentation and surgical management of obstruction to the upper urinary tract
- The pathophysiology of renal stone formation
- The management of urinary tract calculi
- The management of sepsis in the upper urinary tract
- Important renal neoplasms and their presentation
- The surgery of upper urinary tract tumours

SURGICAL ANATOMY

The parenchyma of each kidney usually drains into seven calyces, three upper, two middle and two lower calyces (Figure 75.1). Each of the three segments represents an anatomically distinct unit with its own blood supply. One or more renal arteries are present as physiological end arteries that provide the sole blood supply to the tissue they serve. The renal veins are commonly multiple, variable and richly anastomotic. When approached anteriorly, the main artery is typically hidden behind the renal vein.

Figure 75.1 The arrangement of renal calyces.

CONGENITAL ABNORMALITIES OF THE KIDNEY**Absence of one kidney**

About one in 1400 people have a single kidney (Table 75.1). Sometimes a ureter and renal pelvis are present with no kidney. The contralateral kidney is typically hypertrophied. The possible absence of the contralateral kidney must be considered when planning nephrectomy.

Renal ectopia

Ectopic kidneys are found in one in 1000 people, usually on the left near the pelvic brim. The other kidney is generally normal. A diseased ectopic kidney may present diagnostic problems and may be mistakenly excised as an unexplained pelvic mass.

Horseshoe kidney

A horseshoe kidney is a pair of ectopic kidneys fused usually at their lower poles and lying in front of the fourth lumbar vertebra

and great vessels. It is found in one in 1000 necropsies and is more common in men. Upper pole fusion is rare.

Clinical features

Horseshoe kidneys are vulnerable to disease, possibly because the ureters are angulated (Figure 75.2) causing urinary stasis, infection and nephrolithiasis. A pelviureteric junction obstruction (see below) has the same consequences. Horseshoe kidney is usually a radiological diagnosis. Usually the urogram shows the lower pole calyces bilaterally point towards the midline. Rarely, all or most of the calyces are reversed (Figure 75.3). Horseshoe kidney is not a contraindication to pregnancy but may predispose to urinary complications.

Division of the relatively avascular isthmus between the kidneys is usually only indicated in the course of surgery for abdominal aortic aneurysm. The blood supply of the horseshoe comes unpredictably from nearby major vessels (Summary box 75.1).

Table 75.1 Congenital abnormalities of the kidney and ureter.

Renal agenesis	
Renal ectopia	Pelvic kidney Horseshoe kidney Crossed dystopia Infantile polycystic disease Unilateral multicystic dysplastic kidney
Aberrant renal vessels	Multiple renal arteries and veins
Duplication	Duplex kidney Duplex renal pelvis Duplex kidney and ureter
Others	Congenital hydronephrosis Retrocaval ureter Congenital megaureter

Summary box 75.1

Horseshoe kidneys

- Horseshoe kidneys are liable to pelviureteric obstruction, infection and stone
- An unrecognised pelvic kidney may cause diagnostic confusion during surgery

Unilateral fusion

Unilateral fusion (synonyms: crossed dystopia, cross fused renal ectopia) is rare but the urogram is striking. Both kidneys are in one loin and usually fused. The ureter of the lower kidney crosses the midline to enter the bladder on the contralateral side. Both renal pelves can lie one above each other medial to the renal parenchyma (unilateral long kidney) or the pelvis of the crossed kidney faces laterally (unilateral S-shaped kidney; Figure 75.4).

Figure 75.2 Horseshoe kidney. Note the ureters passing in front of the fused lower poles.

Congenital cystic kidneys

Congenital cystic kidneys (synonym: polycystic kidneys) are hereditary, potentially lethal and transmitted by either parent as an autosomal dominant trait. Thus, the risk of inheriting the condition is high. The disease does not usually manifest clinically before the age of 30 years.

Pathology

The kidneys are huge: the cysts distort the renal capsule. Cysts of various sizes contain clear fluid, thick brown material or coagulated blood. There may be a congenital cystic disease of the liver. The aetiology is uncertain.

Clinical features in the adult

The condition is slightly more common in women than men. There are six clinical features:

- 1 an irregular upper quadrant abdominal mass;
- 2 loin pain;
- 3 haematuria;
- 4 infection;
- 5 hypertension;
- 6 uraemia.

Renal enlargement

Less florid examples are revealed unexpectedly at laparotomy or on abdominal imaging. Unilateral renal swelling, in which one kidney contains larger cysts than the other, may be confused with a cystic renal tumour.

Pain

Pain is commonly a dull loin ache. Haemorrhage into a cyst causes more severe pain, as does a calculus passing from the diseased kidney.

Haematuria

Cyst rupture into the renal pelvis may cause recurrent haematuria. Profuse haematuria is uncommon.

Infection

Pyelonephritis is common in patients with congenital cystic kidney, presumably because of urinary stasis.

Figure 75.3 Urogram of a horseshoe kidney. Only rarely are all the calyces directed towards the spinal column.

Figure 75.4 Unilateral S-fusion of the kidneys.

Hypertension

After the age of 20 years, most patients are hypertensive.

Uraemia

Congenital cystic kidneys produce large volumes of poor quality urine with a trace of albumin but no casts or cells. Non-specific symptoms of chronic renal failure develop as functioning renal tissue is replaced by cysts. Severe anaemia is common. Signs of renal failure often begin in middle life and the patient soon needs renal replacement therapy.

Imaging

There are multiple cysts in both kidneys and sometimes cysts in the liver and other organs. Blood and debris in the cysts may mimic the heterogeneity of a cystic adenocarcinoma. Simple cysts are usually solitary and have smooth thin walls and homogeneous contents (Figure 75.5). Cytologic examination of cyst fluid obtained by fine-needle aspiration will rule out cancer.

The urogram is typical: the renal shadows are enlarged in all directions; the renal pelvis is compressed and elongated; and the calyces are stretched over the cysts (Figure 75.6).

Treatment

As kidney failure develops, a low-protein diet postpones the inevitability of renal replacement therapy. Infection, anaemia, hypertension and disturbances of calcium metabolism also need treatment by a nephrologist.

Surgery to uncap the cysts (Rovsing's operation) is rarely indicated (Summary box 75.2).

Summary box 75.2

Polycystic kidney disease

- Inherited as an autosomal dominant trait
- An important cause of end-stage renal failure
- Pain, haematuria, infection and hypertension are common
- Often fatal in early middle age

Infantile polycystic disease

Infantile polycystic disease is a rare autosomal recessive condition. The kidneys are large and may obstruct birth. Many patients are stillborn or die from renal failure early in life. In

some children, associated congenital hepatic fibrosis is a major problem.

Unilateral multicystic disease

Multicystic dysplastic kidney is more common. It presents as a mass in the flank. Excision is the treatment of choice. Wilms' tumour (see below), neuroblastoma and congenital hydronephrosis are all rarer childhood causes of flank masses.

Simple cyst of the kidney

Simple renal cysts are often discovered incidentally on imaging: they rarely give symptoms and are often multiple (Figure 75.5). A palpable mass, pain from haemorrhage into the cyst and infection are uncommon presentations. Occasionally, a cyst in the hilum of the kidney (a parapelvic cyst) presses on the pelviureteric junction and causes obstruction.

The true nature of a cyst will be apparent by its appearance on ultrasound or computed tomography (CT). Percutaneous cyst puncture for cytology is rarely necessary (Summary box 75.3).

Summary box 75.3

Simple renal cysts

- Common
- Often multiple
- Diagnosed on ultrasound
- Rarely require treatment
- Treat only if causing obstruction

Differential diagnosis

In sheep-rearing districts, hydatid cysts of the kidney are common. On the right side, they can be mistaken for a hydatid cyst of the liver. Occasionally, the patient complains of passing 'grape skins' (ruptured daughter cysts) in the urine. Removal of the cyst must follow the principles used in excision of hydatid cyst of the liver. For a large cyst, nephrectomy may be safer.

Figure 75.5 Simple cyst (C) of the lower pole shown on a longitudinal ultrasound scan of the kidney.

Figure 75.6 Polycystic kidney: urographic appearance. Note the length of the kidney and the bell-like calyces stretched over the cysts.

Aberrant renal vessels

Multiple renal arteries are most common on the left. The renal arteries are functional end-arteries, so division of an aberrant renal artery leads to infarction of a section of parenchyma. Aberrant renal veins are common and can be divided with impunity. Aberrant arteries probably do not cause hydronephrosis, although a hydronephrotic renal pelvis may bulge between renal vessels, making them noticeable (Figure 75.7).

CONGENITAL ABNORMALITIES OF THE RENAL PELVIS AND URETER

Duplication of a renal pelvis

Duplication of a renal pelvis, usually unilateral and left-sided (Figure 75.8), is found in about 4 per cent of patients. The small upper renal pelvis drains the upper calyces; the larger lower renal pelvis drains the middle and lower groups of calyces.

Duplication of a ureter

Duplicated ureter is found in about 3 per cent of urograms often joining in the lower third of their course (Figure 75.9) with a common ureteric orifice. When the ureters open independently into the bladder, the ureter from the upper pelvis opens distally and medially (Figure 75.10).

Clinical features

Infection, calculus formation and pelviureteric junction obstruction are more common than in normal kidneys but most are discovered by chance. One moiety may be dysplastic and non-functioning. Two ureters opening separately may both be abnormal in function, position or both. In children, this may result in a refluxing lower pole ureter and an upper pole ureter terminating in a ureterocele with a risk of infection and/or obstruction.

Figure 75.7 Aberrant accessory renal artery with hydronephrosis. The dilated renal pelvis bulges over the vessel.

An ectopic second ureteric opening is a rare cause of puzzling symptoms. In females, an ectopic ureter opens either into the urethra below the sphincter (Figure 75.11) or into the vagina. The history suggests the diagnosis which is confirmed by urography. A girl or woman who voids normally but who has dribbled urine for as long as she can remember probably has an ectopic ureteric orifice. The orifice is difficult to see because it is guarded by a valve.

In the male, the aberrant opening is above the external urethral sphincter so the patient is continent. The ureteric orifice at the apex of the trigone, the posterior urethra, in a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal, and infection is common.

Treatment

Asymptomatic duplication of the kidney is harmless. A severely diseased or atrophic moiety is effectively treated by partial nephrectomy. A refluxing ureter may need reimplanting. An ectopic ureter in the female frequently drains hydronephrotic and chronically infected renal tissue, which is best excised. Rarely, the incontinence can be cured and renal function preserved by implanting the ectopic ureter into the bladder or contralateral ureter (Summary box 75.4).

Figure 75.8 Urogram showing a left kidney with double pelvis.

Figure 75.9 Retrograde ureterogram showing a double ureter on the left.

Summary box 75.4

Duplication of the kidneys and ureters

- Is commonly asymptomatic and harmless
- One or both moieties may be dysplastic
- There may be urinary reflux, incontinence or obstruction

Congenital megaureter

Congenital megaureter is a rare oddity that may be bilateral and associated with other congenital anomalies. Functional obstruction at the lower end of the ureter ends in progressive dilatation and infection. The ureteric orifice appears normal and a ureteric catheter passes easily. Reflux is not a feature of the untreated condition but occurs if the ureteric orifice is opened endoscopically. Spontaneous improvement occurs but infection or deteriorating function will require refashioning and reimplantation of the affected ureter.

Post-caval ureter

The right ureter passes behind the vena cava instead of lying to the right. If this causes obstructive symptoms, the ureter can be divided and rejoined in front of the cava. Unusually, the retro-caval portion of the ureter is fibrotic and must be excised.

Ureterocele

Ureterocele is a cystic enlargement of the intramural ureter, probably due to congenital atresia of the ureteric orifice. Present from childhood, the condition is often unrecognised until adult life. The 'adder head' on excretory urography (Figure 75.12) is

Adder head. An adder is a venomous snake of the family Viperidae which is found in the UK and other parts of the world. It has a triangular shaped head.

Figure 75.10 Complete ureteric duplication. Two ureteric orifices are seen on cystoscopy: the lower and more medial drains the upper renal pelvis.

typical. Ureterocele is confirmed by the cystoscopic appearance of a translucent cyst enlarging and collapsing as urine flows in to it (Figure 75.13). Treatment should be avoided unless there are symptoms arising from infection and/or stone formation. Ureterocele is most common in women; occasionally, the cyst may cause obstruction to the bladder outflow by prolapsing into the internal urethral opening.

Endoscopic diathermy incision is effective treatment for a symptomatic ureterocele, although a micturating cystogram is advisable to detect postoperative urinary reflux. In advanced unilateral cases with hydronephrosis or pyonephrosis, consider nephrectomy.

INJURIES TO THE KIDNEY

In civilian life, injuries to the kidney result most often from either blows or falls on the loin or crushing injury to the abdomen, typically in a road traffic accident. Haematuria after trivial injury to the kidney should suggest the possibility of a pre-existing disease, e.g. calculus, hydronephrosis or tuberculosis.

The range of injury extends from a small sub-capsular haematoma to a complete tear through the kidney (Figure 75.14).

Figure 75.11 In women, one ureteric orifice may open below the sphincter, causing intractable incontinence of urine.

Figure 75.12 Adder-head appearance of a ureterocele.

The kidney may be partially or wholly torn from its vascular pedicle; one pole may be completely detached.

Closed renal injury is usually extraperitoneal. In young children with little extraperitoneal fat, the peritoneum, which is closely applied to the kidney, can tear with the renal capsule, leaking blood and urine into the peritoneum (Summary box 75.5).

Summary box 75.5

Haemorrhage

- Lethal haemorrhage is a serious risk in kidney trauma

Figure 75.13 Ureterocele on cystoscopy.

Figure 75.14 Types of closed renal trauma: (a) subscapular haematoma; (b) laceration; (c) avulsion of one pole; (d) avulsion of the renal pedicle.

Clinical features of closed renal trauma

There is local pain and tenderness, sometimes with superficial soft-tissue bruising.

Haematuria

Haematuria may not appear until days after the injury. Profuse bleeding may cause clot colic.

Severe delayed haematuria

Sudden haematuria between the third day and third week after trauma in a recovering patient is caused by a clot becoming dislodged.

Meteorism

Abdominal distension 24–48 hours after renal injury is probably a result of retroperitoneal haematoma implicating splanchnic nerves (Summary box 75.6).

Summary box 75.6

Clinical features of closed renal trauma

- There may be no external bruising
- Haematuria indicates kidney damage and should prompt careful monitoring and urgent investigation
- Delayed haemorrhage may occur

Management and treatment

Watchful treatment of closed renal trauma is often successful. Consider the possibility of injury to other organs at an early stage.

- Cross-match blood and secure intravenous access if there is any evidence of hypovolaemic shock or continuing haemorrhage.
- Advise bed-rest while there is macroscopic haematuria and restrict activity for a week after the urine clears.
- Administer appropriate analgesia.
- Keep hourly observations.
- Antibiotics should be given to prevent infection of the haematoma.
- Check the urine passed for haematuria and chart the result.
- Urgent intravenous urography (IVU) or contrast-enhanced CT will clarify the extent of renal damage and show that the other kidney is normal.
- Blood should be sent for grouping and serum saved for cross-matching in all cases.

Surgical exploration

Surgical exploration is necessary in less than 10 per cent of closed injuries; it is indicated if there is progressive blood loss or there is an expanding loin mass. The aim is to stop bleeding while conserving as much renal tissue as possible. A renal arteriogram performed preoperatively will help to frame an operative strategy. Embolisation may arrest the haemorrhage if a bleeding vessel can be identified.

Damage to other abdominal organs is checked during a transperitoneal approach. Release of the tamponading effect of the perirenal haematoma can result in massive haemorrhage and the surgeon must be prepared for this. When the kidney is irretrievably ruptured or avulsed from its pedicle, nephrectomy is the only course. Small tears can be sutured over a haemostatic sponge or a piece of detached muscle. Large single rents in the kidney are best dealt with by passing a tube nephrostomy through the defect and suturing the renal tissue around it. Partial nephrectomy may be practicable for localised injury.

When a solitary kidney is sufficiently damaged to need exploration, it must be repaired. Failing this, the wound is packed firmly with gauze to stop the bleeding in the hope that some renal function may be retained when the ruptured kidney heals (Summary box 75.7).

Summary box 75.7

Surgical treatment in closed renal trauma

- Exploration of the kidney may be associated with massive blood loss as the haematoma is opened
- Check that the contralateral kidney is functioning because nephrectomy is a possibility

Complications

Heavy haematuria may lead to clot retention requiring bladder washout.

Pararenal pseudohydronephrosis may occur weeks later from a combination of complete cortical tear and ureteric obstruction caused by scarring.

Hypertension, resistant to drugs, resulting from renal fibrosis, may occur long after injury. Nephrectomy may be necessary.

Post-traumatic aneurysm of the renal artery (Figure 75.15) is rare. There is loin pain and a non-tender swelling may be felt if the aneurysm is large. Congestion of the parenchyma leads to intermittent haematuria. Aortography is diagnostic. Excision

or nephrectomy is indicated to prevent fatal rupture of the aneurysm.

INJURIES TO THE URETER

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduced urine output. An IVU or contrast-enhanced CT shows extravasation of contrast.

Injury to one or both ureters during pelvic surgery

This occurs most often during vaginal or abdominal hysterectomy when the ureter is mistakenly divided, ligated, crushed or excised. Pre-emptive ureteric catheterisation makes it easier to identify the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient's condition is poor. Deliberate ligation of the proximal ureter and temporary percutaneous nephrostomy is then the best course until the patient is well enough for a repair (Summary box 75.8).

Summary box 75.8

Ureteric injury during operation

- Surgical trauma during pelvic surgery is the most common cause of ureteric trauma
- Preoperative catheterisation of the ureters makes them easier to protect
- Injuries discovered during surgery should be repaired immediately

Figure 75.15 Aneurysm of the renal artery containing lamellated thrombus.

Injury not recognised at the time of operation

Unilateral injuries

There are three possibilities:

- 1 **No symptoms.** Ligation of a ureter may lead to silent atrophy of the kidney. The injury may be unsuspected until the patient undergoes urological imaging.
- 2 **Loin pain and fever,** possibly with pyonephrosis, occur with infection of the obstructed system. Loss of function will be permanent unless obstruction is relieved by promptly inserting a percutaneous nephrostomy.
- 3 **A urinary fistula** develops through the abdominal or vaginal wound. The IVU or contrast-enhanced CT shows extravasation with or without obstruction of one or both ureters. Nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided, but delayed repair often leaves the patient incontinent. Early repair is safe if the patient is fit for surgery.

Bilateral injury

Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent nephrostomy or immediate surgery is essential.

Repair of the injured ureter

An open repair may be avoidable if a stent will pass the obstruction (Table 75.2). If the cut ends of the ureter can be apposed without tension, they should be joined by a spatulated anastomosis over a double pigtail catheter.

If the division is low, the bladder may be hitched and the ureter can be reimplanted. Extra length may be obtained by mobilising the kidney.

In the Boari operation (Figure 75.16), a flap of bladder wall is fashioned into a tube to replace the lower ureter. The disadvantage of implanting the ureter end to side into the contralateral ureter (a transureteroureterostomy) is that it risks converting a unilateral injury into a bilateral one.

Figure 75.16 Boari operation: a strip of bladder wall is fashioned into a tube to bridge the gap between the cut ureter and the bladder.

Achille Boari, 19th century Italian, urological surgeon from Ferrara; he described the technique of a bladder flap in dogs in 1894; it was first performed in a patient in 1936.

Table 75.2 Methods for repairing a damaged ureter.

If there is no loss of length	Spatulation and end-to-end anastomosis without tension
If there is little loss of length	Mobilise kidney Psoas hitch of bladder Boari operation
If there is marked loss of length	Transureteroureterostomy Interposition of isolated bowel loop or mobilised appendix Nephrectomy

Nephrectomy may be best when the patient's outlook is poor and the other kidney is normal. When conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary (Summary box 75.9).

Summary box 75.9

Repair of ureteric injury

When surgical damage to a ureter is discovered postoperatively:

- Repair need not be delayed
- Ideally surgical repair should be performed by a urologist

HYDRONEPHROSIS

Hydronephrosis is an aseptic dilatation of the kidney caused by obstruction.

Unilateral hydronephrosis

See Summary box 75.10.

Summary box 75.10

Causes of unilateral ureteric obstruction

Extramural obstruction

- Tumour from adjacent structures, e.g. cervix, prostate, rectum, colon or caecum
- Idiopathic retroperitoneal fibrosis
- Retrocaval ureter

Intramural obstruction

- Congenital stenosis, physiological narrowing of the pelviureteric junction leading to pelviureteric junction obstruction
- Ureterocele and congenital small ureteric orifice
- Inflammatory stricture following removal of ureteric calculus, repair of a damaged ureter or tuberculous infection
- Neoplasm of the ureter or bladder cancer involving the ureteric orifice

Intraluminal obstruction

- Calculus in the pelvis or ureter
- Sloughed papilla in papillary necrosis (especially in diabetics, analgesic abusers and sickle cell disease)

Bilateral hydronephrosis

Bilateral hydronephrosis is usually the result of urethral obstruction, but the lesions described above may occur bilaterally.

When due to lower urinary obstruction, the cause may be:

- congenital:
 - posterior urethral valves;
 - urethral atresia;
- acquired:
 - benign prostatic enlargement or carcinoma of the prostate;
 - postoperative bladder neck scarring;
 - urethral stricture;
 - phimosis.

The ureters can be obstructed in their intramural course by detrusor hypertrophy caused by urethral obstruction.

Pathology

There is calyceal dilatation and pressure atrophy of the kidney. A kidney destroyed by longstanding hydronephrosis is a thin-walled, lobulated, fluid-filled sac.

Clinical features

Unilateral hydronephrosis

Unilateral hydronephrosis (commonly caused by idiopathic pelviureteric junction obstruction or calculus) is more common in women and on the right.

Presenting features include the following:

- Mild pain or dull aching in the loin, often a dragging heaviness worsened by excessive fluid intake. The kidney may be palpable.
- Intermittent hydronephrosis (Dietl's crisis). Loin swelling is associated with acute renal pain. The pain goes and the swelling disappears when a large volume of urine is passed.
- Antenatal detection in the fetus by ultrasound scan. Many of these cases are benign, but postnatal investigation is required to detect those with significant pelviureteric junction obstruction (Summary box 75.11).

Summary box 75.11

Idiopathic pelviureteric obstruction

- May be asymptomatic
- Can present as intermittent loin pain often exacerbated by a fluid load

Bilateral hydronephrosis

From lower urinary obstruction

Symptoms of bladder outflow obstruction predominate. The kidneys are usually impalpable because renal failure intervenes before they enlarge.

From bilateral upper urinary tract obstruction

Idiopathic retroperitoneal fibrosis affects both ureters and idiopathic pelviureteric junction obstruction can be bilateral. Symptoms may be referred to one side.

From pregnancy

Dilatation of the ureters and renal pelves occurs early in pregnancy up to the 20th week. It results from the effects on the ureteric smooth muscle of high levels of circulating progesterone and is part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. This physiological condition is associated with an increased liability to infection and there is a possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction (Summary box 75.12).

Summary box 75.12

Ureteric dilatation in pregnancy

- Physiological dilatation of the ureter is common in pregnancy

Imaging

Ultrasound scanning (Figure 75.17) is the least invasive means of detecting hydronephrosis and is regularly used to diagnose pelviureteric junction obstruction *in utero*.

IVU helps only if there is significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become 'clubbed'. If the level of obstruction is in doubt, it can help to take follow-up films 36 hours after the contrast has been injected. Contrast slowly diffuses to fill the obstructed system down to the blockage.

Isotope renography is the best test to confirm obstructive dilatation of the collecting system. A substance (usually diethylenetriaminepenta-acetic acid (DTPA) or MAG-3) is injected intravenously. The DTPA is labelled with technetium-99m, a gamma-ray emitter, so that the passage of 99mTc-labelled DTPA through the kidneys can be tracked using a gamma camera. 99mTc-DTPA is cleared from a normal kidney but stays

Figure 75.17 Ultrasound of a hydronephrotic kidney. A, artery; C, calyces; P, pelvis.

Figure 75.18 Isotope renogram series shows a late accumulation and persistence of radioactivity in the left kidney (the image is a posterior view).

in the renal pelvis on the obstructed side and is retained even if urine flow is increased by administering frusemide (Figure 75.18).

Very occasionally, a Whitaker test is indicated. A percutaneous puncture of the kidney is made and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography (Figure 75.19) is rarely indicated but will confirm the site of obstruction immediately before corrective surgery (Summary box 75.13).

Summary box 75.13

Imaging

- Obstruction of the ureter is diagnosed by a combination of ultrasound scanning and isotope renography
- An obstructed kidney is worth preserving if it is contributing more than 20 per cent of total renal function

Figure 75.19 Retrograde ureteropyelogram showing hydronephrosis with greatly enlarged pelvis and dilated 'clubbed' calyces.

Treatment

The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Nephrectomy should be considered only when the kidney has been largely destroyed. Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

Pyeloplasty

In the Anderson–Hynes operation (Figure 75.20), the upper third of the ureter and the renal pelvis are mobilised. A renal vein overlying the distended pelvis can be divided, but an artery in this situation should be preserved to avoid infarction of the territory that it supplies. The anastomosis is made in front of such an artery. A nephrostomy tube or a ureteric stent protects the anastomosis. Laparoscopic pyeloplasty is becoming increasingly popular.

Endoscopic pyelolysis

Disruption of the pelviureteric junction by a balloon passed up the ureter and distended under radiographic control has been used to treat idiopathic pelviureteric junction obstruction.

Figure 75.20 (a–e) Anderson–Hynes disjunction pyeloplasty.

Robert Whitaker, urologist, Addenbrooke's Hospital, Cambridge, UK.

James Christie Anderson, 1899–1984, urologist, The Royal Hallamshire Hospital, Sheffield, UK.

Wilfred Hynes, 1903–1991, plastic surgeon, The Plastic and Jaw Department, The Royal Sheffield Hospital, Sheffield, UK. Anderson and Hynes devised the operation in 1949. It is nowadays done laparoscopically, particularly in children. Robotically assisted laparoscopic dismembered pyeloplasty has also been carried out.

The long-term efficacy of this and various forms of endoscopic pyelotomy has still to be proved. The alternative minimal access procedure, laparoscopic pyeloplasty, is increasingly popular.

RENAL CALCULI

Aetiology

This subject is complex and the following represents a brief summary of current opinion.

Dietetic

Deficiency of vitamin A causes desquamation of epithelium forming a nidus on which a stone is deposited. This mechanism is probably active in the formation of bladder calculi.

Altered urinary solutes and colloids

Dehydration concentrates urinary solutes until they precipitate. Reduction of urinary colloids, which adsorb solutes, or mucoproteins, which chelate calcium, might tend to crystal and stone formation.

Decreased urinary citrate

The presence of citrate in urine, 300–900 mg per 24 hours (1.6–4.7 mmol per 24 hours) as citric acid, keeps relatively insoluble calcium phosphate and citrate in solution.

Renal infection

Infection favours the formation of urinary calculi. Clinical and experimental stone formation are common when urine is infected with urea-splitting streptococci, staphylococci and especially *Proteus* spp.

Inadequate urinary drainage and urinary stasis

Stones are liable to form when urine is static.

Prolonged immobilisation

Immobilisation is liable to result in skeletal decalcification and an increase in urinary calcium favouring the formation of calcium phosphate calculi.

Figure 75.21 Oxalate calculi. The larger one removed from the right kidney is blackened by the deposition of altered blood.

Hyperparathyroidism

Hyperparathyroidism leading to hypercalcaemia and hypercalciuria is found in 5 per cent or less of those who present with radio-opaque calculi. In cases of recurrent or multiple stones, this cause should be eliminated by appropriate investigations (see Chapter 51). A parathyroid adenoma should be removed before definitive treatment for the urinary calculi.

Types of renal calculus

Oxalate calculus (calcium oxalate)

Oxalate stones are irregular with sharp projections (Figure 75.21). A calcium oxalate monohydrate stone is hard and radiodense.

Phosphate calculus

A phosphate calculus (calcium phosphate often with ammonium magnesium phosphate (struvite)) is smooth and dirty white. It grows in alkaline urine, especially when urea-splitting *Proteus* organisms are present. The calculus may enlarge to fill most of the collecting system, forming a stag-horn calculus (Figure 75.22). Even a large stag-horn calculus may be asymptomatic for years until it presents with haematuria, urinary infection or renal failure.

Uric acid and urate calculi

These are hard, smooth and often multiple and multifaceted. Pure uric acid stones are radiolucent. CT will distinguish them from other causes of filling defects including tumours of the ureter. Most uric acid stones contain some calcium, so they cast a faint radiological shadow.

Cystine calculus

An uncommon congenital error of metabolism leads to cystinuria. Cystine stones are often multiple and may grow to form a cast of the collecting system. Cystine stones are radio-opaque and very hard.

Figure 75.22 Stag-horn calculus.

The first nephrolithotomy was performed by **Ambrose Paré** (1509–1590) on a prisoner condemned to death by hanging. Paré cut out two stones from his kidney following which he was cured. As he recovered from this procedure, he secured remission from his death penalty and was given a grant of money. Paré said: 'I dressed his wounds, but God healed them'.

Clinical features

Renal calculi are common. Approximately 50 per cent of patients present between the ages of 30 and 50 years. The male–female ratio is 4:3 (Summary box 75.14).

Summary box 75.14

Renal stones

- Are common
- May be clinically silent even when large
- Are usually visible on a plain abdominal radiograph
- May be radiolucent when composed of uric acid

Silent calculus

Renal failure may be the first indication of bilateral silent calculi, although secondary infection usually produces symptoms first.

Pain

Pain occurs in 75 per cent of people with urinary stones. Fixed renal pain occurs in the renal angle (Figure 75.23), the hypochondrium, or in both. It may be worse on movement.

Ureteric colic is an agonising pain passing from the loin to the groin. Pain resulting from renal stones rarely lasts more than 8 hours in the absence of infection. There is no pyrexia, although the pulse rate rises because of the severe pain. Ureteric colic is often caused by a stone entering the ureter but it may also occur when a stone becomes lodged in the pelviureteric junction. The severity of the colic is not related to the size of the stone (Summary box 75.15).

Summary box 75.15

Ureteric colic

- Severe exacerbations on a background of continuing pain
- Radiates to the groin, penis, scrotum or labium as the stone progresses down the ureter
- Severity of pain is not related to stone size
- Haematuria is very common
- There may be few physical signs

Abdominal examination

During an attack of ureteric colic, rigidity may be present but not prominent. Percussion over the kidney produces a stab of pain and there may be tenderness on gentle deep palpation. Hydronephrosis or pyonephrosis leading to a palpable loin swelling is rare.

Haematuria

Haematuria, usually small in amount, is common and sometimes is the only symptom of stone disease.

Pyuria

Infection is particularly dangerous when the kidney is obstructed. Pressure builds in the system, organisms are forced into the circulation and a septicaemia can quickly develop.

Figure 75.23 The usual distribution of renal pain.

Stones may cause pyuria by irritating the urothelium even in the absence of infection.

Investigation of suspected urinary stone disease

X-ray

The 'KUB' film shows the kidney, ureters and bladder. A branched stone is unmistakable. (Figure 71.24). An opacity maintaining its position relative to the urinary tract during respiration is likely to be a calculus.

Calcified mesenteric nodes and opacities within the gut will be anterior to the vertebral bodies on a lateral x-ray and thus outside the urinary tract (Summary box 75.16).

Summary box 75.16

Opacities on a plain abdominal radiograph that may be confused with renal calculus

- Calcified mesenteric lymph node
- Gallstones or concretion in the appendix
- Tablets or foreign bodies in the alimentary canal (e.g. cyclopentiazide (Navidrex-K))
- Phleboliths – calcification in the walls of veins, especially in the pelvis
- Ossified tip of the 12th rib
- Calcified tuberculous lesion in the kidney
- Calcified adrenal gland

Contrast-enhanced CT

CT, preferably spiral, has become the mainstay of investigation of acute ureteric colic.

Excretion urography

IVU will establish the presence and position of a calculus and the function of the other kidney.

Ultrasound scanning

Ultrasound scanning is of most value in locating stones for treatment by extracorporeal shock wave lithotripsy (ESWL) (see below).

Surgical treatment of urinary calculi

Conservative management

Calculi smaller than 0.5 cm pass spontaneously unless they are impacted. Surgical intervention should be avoided. Small renal calculi may cause symptoms by obstructing a calyx or acting as a focus for secondary infection. Most can be safely observed until they pass (Summary box 75.17).

Summary box 75.17

Management of small stones

- Most small urinary calculi will pass
- Infection in an upper urinary tract obstructed by stone is dangerous and needs urgent surgical intervention

Preoperative treatment

Antibiotic treatment starts before surgery and continues afterwards.

Operation for stone

Most stones should be treated by minimal access and minimally invasive techniques. Open operations are still needed when appropriate expertise is not available or newer techniques have failed (Summary box 75.18).

Summary box 75.18

Kidney stone removal

- Most urinary calculi can be treated by minimal access techniques

Modern methods of stone removal

Kidney stones

Percutaneous nephrolithotomy

Endoscopic instruments are passed into the kidney by a percutaneous technique (Figure 75.25). Small stones may be grasped under vision and extracted whole. Larger stones are fragmented by an ultrasound, laser or electrohydraulic probe and removed in pieces.

Figure 75.24 Plain abdominal x-ray showing complete stag-horn calculi.

The aim is to remove all fragments. A nephrostomy drain is left in the system when the procedure is complete. This decompresses the kidney and allows repeated access if necessary. Percutaneous nephrolithotomy is sometimes combined with ESWL in the treatment of complex (stag-horn) calculi.

Complications of percutaneous nephrolithotomy include: (1) haemorrhage from the punctured renal parenchyma; (2) perforation of the collecting system with extravasation of saline irrigant; (3) perforation of the colon or pleural cavity during placement of the percutaneous track.

Extracorporeal shock wave lithotripsy

Crystalline stones disintegrate under the impact of shock waves produced by the ESWL machine.

The shocks may be aimed by ultrasound or x-ray imaging (Figure 75.26). The devices also differ in the disruptive force that they can develop. Less powerful machines break stones less effectively and several treatments may be necessary. Weaker shocks hurt less and treatment can be given without general anaesthesia.

Ureteric colic is common after ESWL, and the patient needs analgesia, usually in the form of a non-steroidal anti-inflammatory drug. Bulky stone fragments may impact in the ureter, causing obstruction. To avoid this, a stent should be placed in the ureter to drain the kidney while stone fragments pass. Occasionally, impacted fragments have to be removed ureteroscopically (see below).

The principal complication of ESWL is infection. Many calculi contain bacteria, which are released from the broken stone. It is wise to give prophylactic antibiotics before ESWL, and an obstructed system should be decompressed by a ureteric stent or percutaneous nephrostomy before treatment.

The clearance of stone from the kidney will depend upon the consistency of the stone and its site. Most oxalate and phosphate stones fragment well and, if lying in the renal pelvis, will clear within days. The results with harder stones, especially cystine stones, are less satisfactory. When treating calyceal stones, the patients should be warned that the clearance may take months.

Open surgery for renal calculi

Operations for kidney stone are usually performed via a loin or lumbar approach (Figure 75.27). All of the procedures are difficult unless the kidney is fully mobilised and its vascular pedicle controlled. A sling should be placed around the upper ureter to stop stones migrating downwards.

Pyelolithotomy

Pyelolithotomy is indicated for stones in the renal pelvis. When the wall of the renal pelvis has been dissected from its surrounding fat, an incision is made in its long axis directly on to the stone. The stone is removed with gallstone forceps. Stone fragments in peripheral calyces may be detected by direct palpation or by intraoperative x-ray or nephroscopy. If there is sepsis, a nephrostomy is essential to drain the system.

Extended pyelolithotomy

The plane between the renal sinus and the wall of the collecting system is developed on the posterior surface of the kidney. This avoids major vessels and allows incisions into the calyces so that even large stag-horn stones can be removed intact.

Figure 75.25 Percutaneous renal stone removal. (a) The stone is in the right renal pelvis. (b) Placement of a cannula under radiological control into the renal pelvis and through it a balloon catheter to stop fragments migrating into the upper ureter. (c) The stone is disrupted by contact lithotripsy and the fragments have been successfully removed by irrigation. (d) A nephrostogram confirms that the renal pelvis is intact.

Nephrolithotomy

If there is a complex calculus branching into the most peripheral calyces, it may be necessary to make incisions into the renal parenchyma to clear the kidney. Nephrolithotomy may also be necessary when the adhesions from previous surgery complicate access to the renal pelvis. The renal pedicle is temporarily cross-clamped to reduce bleeding from the vascular renal tissue. Incisions are made posterior and parallel to the most prominent part of the convex renal border, where the territories of the anterior and posterior branches of the renal artery meet (Brödel's line). Cooling the kidney extends the ischaemia. Nephrolithotomy incisions must be closed with haemostatic sutures and the patient observed for signs of reactionary haemorrhage.

Partial nephrectomy is sometimes preferable for a stone in the lowermost calyx with infective damage to the adjacent parenchyma.

A functionless kidney destroyed by stone disease should be removed, particularly when there is xanthogranulomatous pyelonephritis. This stone-related inflammatory mass must be removed with care because it is liable to be attached to adjacent structures such as the colon.

Treatment of bilateral renal stones

Usually the kidney with better function is treated first, unless

the other kidney is more painful or there is pyonephrosis which needs urgent decompression.

Prevention of recurrence

Ideally, stone formers should be investigated to exclude metabolic factors, although the diagnostic yield is low in patients with a single small stone. The urine should be screened for infection. The following investigations are appropriate in bilateral and recurrent stone formers:

- serum calcium, measured fasting on three occasions to exclude hyperparathyroidism;
- serum uric acid;
- urinary urate, calcium and phosphate in a 24-hour collection; the urine should also be screened for cystine;
- analysis of any stone passed.

Dietary advice is not usually helpful in avoiding stone recurrence in people who have a balanced diet. Those who consume excessive amounts of milk products (calcium stones), rhubarb, strawberries, plums, spinach and asparagus (calcium oxalate stones) should be advised to be more moderate.

Patients with hyperuricaemia should avoid red meats, offal and fish, which are rich in purines, and should be treated with allopurinol. Eggs, meat and fish are high in sulphur-containing proteins and should be restricted in cystinuria.

Figure 75.26 Extracorporeal shock wave lithotripsy. (a) The patient being placed on the ultrasound lithotripter. (b) Positioning of the patient being checked by ultrasound.

Stone sufferers should drink plenty to keep their urine dilute.

Drug treatment is largely ineffective except in those few patients who are shown to have idiopathic hypercalcaemia. Bendroflumethiazide (5 mg) and a calcium-restricted diet reduce urinary calcium (Summary box 75.19).

Summary box 75.19

Recurrent stone formation

- Stones are more common in those who have had a previous stone
- Unless there is a specific biochemical abnormality, high fluid intake is the best prophylactic measure

dull pain, often in the iliac fossa and increased by exercise and lessened by rest. Distension of the renal pelvis due to obstruction may cause loin pain. The stone may become embedded as the adjacent ureteric wall becomes eroded and oedematous as a result of pressure ischaemia. Perforation of the ureter and extravasation of urine is a rare complication.

Severe renal pain subsiding after a day or so suggests complete ureteric obstruction. If obstruction persists after 1–2 weeks, the calculus should be removed to avoid pressure atrophy of the renal parenchyma.

Haematuria

Almost all ureteric colic is associated with transient microscopic haematuria. Serious bleeding is uncommon and should suggest clot colic.

URETERIC CALCULUS

A stone in the ureter usually comes from the kidney. Most pass spontaneously.

Clinical features

A stone passing down the ureter often causes intermittent attacks of ureteric colic.

Ureteric colic

The waves of agonising loin pain are typically referred to the groin, external genitalia and the anterior surface of the thigh. As the stone enters the bladder, the pain can be referred to the tip of the penis.

Impaction

There are five sites of narrowing where the stone may be arrested (Figure 75.28). An impacted stone causes a more consistent

Figure 75.27 Open operations for renal calculus.

Figure 75.28 Normal anatomical narrowings (1–5) of the ureter.

Abdominal examination

There is tenderness and some rigidity over some part of the course of the ureter. The presence of haematuria does not rule out appendicitis because an inflamed appendix can give rise to a local ureteritis leaking some red cells into the urine. The patient with acute ureteric colic is usually in greater pain and less ill than one with appendicitis or acute cholecystitis.

Imaging

Most urinary calculi are radio-opaque. Stones are difficult to see if small or obscured by bowel contents or nearby bones. IVU while the patient has pain can confirm the diagnosis, although

spiral CT is preferable. In ureteric colic, there will probably be little or no excretion on the affected side. Occasionally, there is an extravasation of contrast from the dilated system. Late x-rays, taken up to 36 hours after the injection of contrast, may show dilatation of the ureter down to an obstructing calculus. A radiolucent uric acid stone may be demonstrated as a filling defect in the contrast-filled system.

Analgesic abusers occasionally fake symptoms to obtain drugs, and emergency imaging is useful in excluding renal colic. If the CT or urogram is normal during an attack, the patient does not have renal colic. The absence of blood in the urine makes colic less likely but its presence can be simulated.

Cystoscopy is not indicated routinely but may reveal oedema around the ureteric orifice when the stone is nearby.

Retrograde ureterography is performed as an immediate preliminary to an endoscopic operation to remove a calculus.

Treatment

Pain

Non-steroidal anti-inflammatory drugs, such as diclofenac and indomethacin, have replaced opiates as the first line of treatment for renal colic. The value of smooth muscle relaxants, such as propantheline (Pro-Banthine), is debatable.

Removal of the stone

Expectant treatment is appropriate for small stones likely to pass naturally (Summary box 75.20). If the patient is not disabled by recurrent attacks of colic, progress can be followed by x-rays every 6–8 weeks.

Summary box 75.20

Indications for surgical removal of a ureteric calculus

- Repeated attacks of pain and the stone is not moving
- Stone is enlarging
- Complete obstruction of the kidney
- Urine is infected
- Stone is too large to pass
- Stone is obstructing solitary kidney or there is bilateral obstruction

Figure 75.29 Dormia stone-catching basket in use: (a) basket introduced past stone; (b) opened; and (c) enclosing stone, ready for withdrawal.

Endoscopic stone removal

Dormia basket

The use of wire baskets under image intensifier control has been replaced by ureteroscopic techniques but they may be useful when the instruments and expertise are not available (Figure 75.29). There is a danger of ureteric injury even with small stones.

Ureteric meatotomy

Endoscopic incision with a diathermy knife will enlarge the opening and free a stone lodged in the intramural ureter. The consequent urinary reflux rarely causes problems.

Ureteroscopic stone removal

A ureteroscope is introduced transurethally across the bladder into the ureter (Figure 75.30) to remove stones impacted in the

ureter. Stones that cannot be caught in baskets or endoscopic forceps under direct vision are fragmented using an electrohydraulic, percussive or laser lithotripter.

Push bang

A stone in the middle or upper part of the ureter can often be flushed back into the kidney using a ureteric catheter. A J-stent secures the calculus in the kidney for subsequent treatment with ESWL.

A flexible fiberoptic ureteroscope can be used for laser destruction of calculi in the renal collecting system or ureter and to retrieve small stones from the kidney.

Lithotripsy *in situ*

A stone in a part of the ureter that can be identified by the imaging system of the lithotripter can be fragmented *in situ*. This form of treatment is not appropriate if there is complete obstruction or if the stone has been impacted for a long time.

Open surgery

Ureterolithotomy

An x-ray confirms the position of the stone immediately before surgery.

The skin incision must be appropriate for the position of the stone. Calculi in the upper third of the ureter are approached through a loin or upper quadrant transverse incision as used for a stone in the renal pelvis. Access to midureteric stones is through a muscle-cutting iliac fossa incision; lower ureteric stones are best reached through a Pfannenstiel incision. For stones close to the bladder, exposure is improved by ligating and dividing the superior vesical vascular pedicle. The ureter is exposed in the retroperitoneum and slings are applied above and below the calculus to stop it from escaping. The ureter is incised longitudinally, directly on to the stone, which is freed by blunt dissection and removed with stone forceps. Soft catheters are passed upwards and downwards to ensure that the ureter is clear. The ureterotomy is closed with interrupted absorbable sutures and a drain left to drain urine leakage. The operation can be performed laparoscopically, but alternative minimal access techniques described above are usually preferable.

IDIOPATHIC RETROPERITONEAL FIBROSIS

In this rare condition, one or both ureters are bound in progressive fibrosis of the retroperitoneal tissues. Most cases are idiopathic but some may be drug related. A similar clinical picture occurs in patients with leaking aortic aneurysm and infiltrating retroperitoneal malignancy.

The patient complains of persistent backache. The onset of anuria and renal failure prompts investigation of the renal tract, which reveals hydronephrosis. The IVU typically shows medial displacement of the ureters and the CT appearances are diagnostic. The sedimentation rate is markedly raised.

Treatment

It may be possible to insert temporary ureteric stents while renal function recovers. If not, percutaneous nephrostomies will drain the obstructed kidneys. Some patients need dialysis. Some

advocate conservative treatment with steroids. Surgery involves dissection of the ureters from their fibrous jacket (ureterolysis). Wrapping omentum around the freed ureters discourages recurrent obstruction.

KIDNEY INFECTIONS

Aetiology

Renal infections arise in the following ways (Summary box 75.21):

- **Haematogenous infection** from a primary site in the tonsils or carious teeth or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by bloodborne spread from lymph nodes in the neck, chest or abdomen.
- **Ascending infection** in the urinary tract is the most common route, and it is most likely to occur when there is vesicoureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

Bacteriology

Escherichia coli and other Gram-negative organisms are commonly responsible. In *E. coli* and streptococcal infections, the urine is acidic. *Proteus* spp. and staphylococci split urea to form ammonia, which makes the urine alkaline and promotes the formation of calculi.

Figure 75.30 Ureteroscopy. X-ray showing a ureteroscope and guidewire in the lower ureter.

Summary box 75.21**Kidney infection**

- Acute pyelonephritis:
 - In childhood
 - In pregnancy
 - With urinary obstruction
- Chronic pyelonephritis:
 - Reflux nephropathy
- Pyonephrosis
- Renal abscess
- Perinephric abscess

Acute pyelonephritis

Acute pyelonephritis is more common in females, especially during childhood, at puberty, after intercourse, during pregnancy and during menopause. It occurs more on the right and is frequently bilateral.

Clinical features

There may be prodromal headache, lassitude and nausea, but the onset of pain is usually sudden, often with a rigor and vomiting. There is acute pain in the flank and hypochondrium. The remitting temperature rises to 39°C or more. The symptoms of cystitis commonly set in, with urgency, frequency and scalding dysuria. There is tenderness in the hypochondrium and in the loin. Rarely, in cases of severe bilateral pyelonephritis, especially when there is an associated obstruction, renal dysfunction may be sufficient to cause uraemia. The risk of life-threatening septicaemia is ever present (Summary box 75.22).

Summary box 75.22**Clinical features of kidney infections**

- More common in women
- Often associated with septicaemia leading to pyrexia and rigors
- Associated with pyuria and occasionally haematuria
- Should be initially treated with broad-spectrum parenteral antibiotics
- Extremely dangerous if the kidney is obstructed

Bacteriological examination of the urine

A midstream urine specimen should be collected into a sterile container; the urine is centrifuged and the sediment examined microscopically. In early acute pyelonephritis, there are usually pus cells and many bacteria. The urine may be misleadingly clear to the eye until the infection becomes established. Culture and sensitivity testing of the causative organisms allows a rational choice of antibiotic, but parenteral treatment with a broad-spectrum antibiotic should be started before the results are available.

Severe cases

There are rigors and a temperature of 40°C or more, often without a corresponding tachycardia. There is vomiting, sweating

and thirst; the patient feels awful. Blood culture is usually positive, especially if the specimen has been taken during a rigor.

Differential diagnosis

It may be difficult to be sure that the patient does not have pneumonia, acute appendicitis or acute cholecystitis. The urgent need is to distinguish acute pyelonephritis from appendicitis, and the site of pain and the presence of marked peritonism are usually helpful. A plain abdominal x-ray may show the outline of a swollen kidney and, if the infection is severe, an ultrasonographer may confirm the appearance of pyelonephritis.

Special cases**Pyelonephritis of pregnancy**

Pyelonephritis of pregnancy usually occurs between the fourth and sixth months of gestation in women with a past history of recurrent urinary infection. In about 10 per cent of cases, the disease runs a severe and protracted course and occasionally leads to abortion or premature birth.

Urinary infection in childhood

Urinary infection in childhood may damage the growing kidney. In young children, symptoms are often non-specific but the child may pass cloudy or offensive urine. The possibility of urinary sepsis should be considered if a child fails to thrive or suffers unexplained pyrexia. Pain or screaming on micturition may occur. The older child may complain of loin pain and may develop urinary frequency and secondary enuresis.

Up to 50 per cent of children with urinary infection have an underlying anatomical abnormality (e.g. reflux or obstruction). The diagnosis of infection is confirmed by examination of a clean-catch specimen or a specimen obtained by suprapubic needle puncture. On culture, a pure growth of more than 10⁵ organisms/mL with a significant pyuria is evidence of infection. Such children should be investigated for underlying urinary tract abnormalities and to assess renal function and scarring.

Vesicoureteric reflux of urine is detectable in about 35 per cent of children with recurrent urinary infection. Renal damage results from the combination of reflux and urinary infection early in life, and reflux nephropathy is a common cause of end-stage renal failure in the UK. Long-term prophylactic antibiotic treatment has become the favoured treatment for recurrent urinary infections resulting from reflux. Surgical reimplantation of the ureters is reserved for those in whom conservative measures fail. However, reimplantation in these patients may fail to cure reflux (Summary box 75.23).

Summary box 75.23**Urinary infection in childhood**

- A single proven urinary infection in a child should prompt referral to a paediatric urologist

Acute pyelonephritis associated with urinary retention

Acute pyelonephritis is a relatively uncommon complication of chronic urinary retention. Often the organisms are introduced

during instrumentation. Patients with a significant postmicturition urinary residue need prophylactic antibiotics to cover transurethral procedures.

Treatment

The treatment of acute pyelonephritis should be prompt, appropriate and prolonged. Investigation to exclude underlying abnormalities in the urinary tract should be undertaken when the acute illness subsides.

While awaiting the bacteriological report and the results of sensitivity tests, a broad-spectrum antibiotic, such as amoxicillin or gentamicin, should be administered, parenterally if necessary. When pain is severe, a morphine-like analgesic drug may be necessary if non-steroidal anti-inflammatory agents are ineffective. The patient should drink copiously; if this is not possible because of nausea and vomiting, an intravenous infusion should be set up.

Most urinary infections acquired outside hospital are sensitive to agents such as trimethoprim and amoxicillin. Hospital-acquired infections are much more likely to be resistant and second-line antibiotics may be needed. Gentamicin and carbenicillin are suitable for infections with more resistant strains of *Pseudomonas pyocyanea*, *Proteus* spp. and *Klebsiella* spp. Ciprofloxacin is particularly useful against *Pseudomonas* spp. in patients who do not have septicaemia. Despite the efficacy of modern antibacterial drugs, recurrent infection is likely if there is an untreated underlying abnormality of the urinary tract such as a stone, vesicoureteric reflux, fistula to the gastrointestinal tract or retention of urine.

Chronic pyelonephritis

Chronic pyelonephritis is often associated with vesicoureteric reflux, sometimes called 'reflux nephropathy', is an important cause of renal damage and end-stage renal failure.

Pathology

There is interstitial inflammation and scarring of the renal parenchyma with a patchy distribution.

Clinical features

The condition is almost three times as common in women as it is in men. Two-thirds of female patients are under 40 years of age, whereas 60 per cent of male patients are over 40.

It is possible, but unusual, for chronic pyelonephritis to remain clinically silent until the symptoms of advanced renal insufficiency appear.

Lumbar pain, dull and non-specific in character, is present in 60 per cent of cases. Increased urinary frequency and dysuria are common. Hypertension, present in 40 per cent of cases, may be of the accelerated ('malignant') type. Tiredness, malaise, anorexia, nausea and headache constitute the main complaint in 30 per cent of cases. The true cause of these nonspecific symptoms may elude diagnosis for years.

Normochromic anaemia due to unsuspected renal impairment is an occasional presenting feature (Summary box 75.24).

Investigations

The glomeruli are relatively preserved so proteinuria is less marked than in glomerulonephritis (<3 g daily). Casts are not usually present but white cells are plentiful.

Summary box 75.24

Chronic pyelonephritis

- A common cause of end-stage renal failure
- Often associated with ureteric reflux
- May be symptomatically silent
- Leads to progressive renal scarring

Escherichia coli, *Streptococcus faecalis*, *Proteus* spp. or *Pseudomonas* spp. are found in the urine.

Treatment

Treatment aims at eradicating predisposing factors such as obstruction or stones and treating the infection, often with repeated courses of antibiotic. Scarred parenchyma is vulnerable to blood-borne organisms and reinfection is likely. Consequently, antibiotics confer only temporary benefit and progressive renal damage is common.

Surgery is indicated only when the disease is confined to one kidney. This is unusual but in such cases nephrectomy or partial nephrectomy may stop the symptoms of infection and make hypertension easier to control. Patients with end-stage renal failure require renal replacement therapy.

Pyonephrosis

Pyonephrosis results from infection of a hydronephrosis, follows acute pyelonephritis or, most commonly, arises as a complication of renal calculus disease. The kidney becomes a multilocular sac containing pus or purulent urine.

Clinical features

The classical triad of symptoms is anaemia, fever and a swelling in the loin. When the condition arises as an infected hydronephrosis, the swelling may be very large and the pyrexia very high and associated with rigors. Symptoms of cystitis may be prominent.

Investigations

Imaging may show a calculus and will demonstrate dilatation of the pus-filled collecting system.

Treatment

Pyonephrosis is a surgical emergency because permanent renal damage and lethal septicaemia threaten. Parenteral antibiotics should be given and the kidney drained. If the pus is too thick to be aspirated through a large percutaneous nephrostomy, consider open nephrostomy. When there is a stone, it should be removed. Nephrectomy may be appropriate when the kidney is destroyed and function on the other side is good.

Renal carbuncle

An abscess may form in the renal parenchyma as the result of blood-borne spread of organisms, especially coliforms or *Staphylococcus aureus*. Renal carbuncle is most commonly seen in diabetics, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency.

Pathology

The renal parenchyma contains an encapsulated necrotic mass.

Clinical features

There is an ill-defined tender swelling in the loin, persistent pyrexia and leukocytosis, simulating a perinephric abscess. Initially there is no pus or bacteria in the urine, but these appear later. The mass in the kidney may be confused with a renal adenocarcinoma (Figure 75.31).

Treatment

Resolution by antibiotic treatment alone is unusual. Formal open incision of the abscess may be necessary if the pus is too thick to be drained by percutaneous aspiration.

Perinephric abscess

The common causes of perinephric abscess are shown in Figure 75.32. Other causes are infection of a perirenal haematoma and perinephric discharge of an untreated pyonephrosis or renal carbuncle. A mycobacterial perinephric abscess may arise by extension from a nearby tuberculous vertebra.

Clinical features

There is swinging pyrexia, abdominal tenderness and fullness in the loin (Figure 75.33). Local signs present early if the infection starts in the lower part of the perinephric fat. Infection at the upper pole is masked by the lower ribs and signs in the loin are less. The white cell count is always markedly raised but there are characteristically no pus cells or organisms in the urine.

Imaging

Ultrasonography and CT are diagnostic.

Treatment

Open drainage may be necessary if the abscess cannot be aspirated through a percutaneous needle. A lumbar incision is made under antibiotic cover large enough to allow the surgeon to open pockets of pus and to explore for an unruptured cortical abscess. Pus is sent for culture and the wound is closed over a tube drain (Summary box 75.25).

Summary box 75.25

Management of perinephric abscess

- Collections of pus in or around the kidney should be drained

Renal tuberculosis

Aetiology and pathology

Tuberculosis of the urinary tract arises from haematogenous infection from a distant focus. The lesions are usually unilateral. Tuberculous granulomas in a renal pyramid coalesce to form an ulcer. Mycobacteria and pus cells discharge into the urine. Untreated lesions enlarge and a tuberculous abscess may form in the parenchyma. The necks of the calyces and the renal pelvis stenosed by fibrosis confine the infection so that there is tuberculous pyonephrosis, sometimes localised to one pole of the kidney. Extension of pyonephrosis or tuberculous renal abscess leads to perinephric abscess and the kidney is progressively replaced by caseous material (putty kidney), which may

Figure 75.31 Longitudinal ultrasound scan through the upper pole of the left kidney demonstrates a renal carbuncle, outlined by crosses. S, spleen.

Figure 75.32 Sources of perinephric abscess.

Figure 75.33 A large perinephric abscess.

be calcified (cement kidney). At any stage, the plain x-ray may show areas of calcification (pseudocalculi). Less commonly, the kidneys may be bilaterally affected as part of the generalised process of miliary tuberculosis (Figure 75.34).

Renal tuberculosis is often associated with tuberculosis of the bladder and typical tuberculous granulomas may be visible in the bladder wall. In men, tuberculous epididymo-orchitis may occur without apparent infection of the bladder.

Clinical features

Renal tuberculosis usually occurs between 20 and 40 years of age, and is more common in men than women.

Urinary frequency is often the earliest symptom and may be the only one. The patient complains of a progressive increase in both daytime and night-time frequency.

'Sterile' pyuria

Routine urine culture is negative but there are white cells in the urine.

Pain

Painful micturition is a feature of tuberculous cystitis. First, there is a suprapubic pain if voiding is delayed; later, a burning pain accompanies micturition. When there is secondary infection, a superadded agonising pain referred to the tip of the penis or to the vulva is often associated with haematuria and strangury.

Renal pain is often minimal but there may be a dull ache in the loin.

Haematuria

In 5 per cent of cases, the first symptom is haematuria occurring from an ulcer on a renal papilla. The tuberculous lesion may be difficult to detect radiologically and mycobacteria may not be cultured from the urine until months later.

A tuberculous kidney is oedematous and friable and is more liable to damage than a normal kidney.

Malaise and weight loss are usual and a low-level evening pyrexia is typical. A high temperature suggests secondary infection or dissemination, i.e. miliary tuberculosis.

On examination

It is unusual for a tuberculous kidney to be palpable. The prostate, seminal vesicles, vasa and scrotal contents should be examined for nodules or thickening (Summary box 75.26).

Figure 75.34 Types of lesion in renal tuberculosis.

Summary box 75.26

Renal tuberculosis

- Consider when symptoms of cystitis continue despite treatment with antibiotics
- Is a cause of 'sterile pyuria'
- Causes chronic inflammation and scarring throughout the urinary tract, which may continue after antituberculous treatment has been instituted
- May cause obstructive lesions throughout the urinary tract

Investigation

Bacteriological

Three complete specimens of early-morning urine should be sent for microscopy and culture before specific chemotherapy is started. Staining of the urine sediment with the Ziehl–Neelsen stain occasionally shows the presence of acid-fast bacilli, but proof that these are pathological mycobacteria must await culture on Löwenstein–Jensen medium. When the clinical picture is convincing, it is permissible to start anti-tuberculous therapy in anticipation of the culture results some 6 weeks later.

X-ray

An abdominal x-ray may show calcified lesions.

Intravenous urography

Early in the disease, the clear-cut outline of a renal papilla may be rendered indistinct by the presence of ulceration. Later, there may be calyceal stenosis (Figure 75.35) and/or hydronephrosis caused by stricture of the renal pelvis or the ureter draining the affected kidney (Figure 75.36). A tuberculous abscess appears

as a space-occupying renal lesion. The bladder may appear shrunken, with its wall irregular or thickened.

Cystoscopy

Cystoscopy is not routine in the investigation of urinary tuberculosis but is often performed because there has been haematuria or unexplained bladder symptoms. The tuberculous urothelium is studded with granulomas that cluster particularly around the ureteric orifices, sometimes with ulceration. As the bladder wall fibroses, the bladder capacity decreases. Contraction of the fibrosed ureter tugs at the ureteric orifice, which is displaced upwards, its mouth wide open (the so-called 'golf-hole' orifice).

Chest x-ray

A chest x-ray will exclude an active lung lesion.

Treatment

Anti-tuberculous chemotherapy is best managed by a specialist. The surgeon must ensure that the state of the urinary tract is reviewed during the first few weeks of therapy because scarring and stricture continue after treatment has started.

Prognosis in renal tuberculosis is good if the patient completes the course of chemotherapy.

Operative treatment

Operative treatment should be conservative, aiming to remove large foci of infection, which are difficult to treat with drugs, and correct the obstruction caused by fibrosis. The optimum time for surgery is between 6 and 12 weeks after the start of anti-tuberculous chemotherapy.

A repertoire of procedures is needed to deal with various potential effects of urinary tuberculosis. An obstructed lower pole calyx may be drained into the upper ureter. A strictured renal pelvis needs a pyeloplasty. Ureteric stenosis and shortening may require a Boari operation or a bowel interposition, depending on the level and extent of the fibrosis. If the kidney has no function it is best to perform a nephroureterectomy (Figure

Figure 75.35 Intravenous urogram showing a small localised tuberculous lesion with hydrocalyx (arrow). Healing took place with conservative treatment.

75.37). A badly contracted bladder may be replaced with a neobladder fashioned from a loop of bowel in a substitution cystoplasty.

NEOPLASMS OF THE KIDNEY

Neoplasms of the kidney are summarised in Summary box 75.27.

Summary box 75.27

Renal neoplasms

Benign neoplasms

- Adenoma
- Angioma
- Angiomyolipoma

Malignant neoplasms

- Wilms' tumour (nephroblastoma in children)
- Grawitz's tumour (adenocarcinoma, hypernephroma)
- Transitional cell carcinoma of the renal pelvis and collecting system
- Squamous cell carcinoma of the renal pelvis

Benign neoplasms

Adenoma

Pea-like cortical adenomas are occasionally discovered. They are asymptomatic and are benign.

Angioma

Angioma may cause profuse haematuria, often in young adults. The bleeding source may be difficult to diagnose without renal angiography.

Angiomyolipoma

Angiomyolipoma is an unusual tumour of the kidney often but not always associated with tuberous sclerosis. Its high fat

Figure 75.36 Retrograde ureterogram showing advanced tuberculosis of the right kidney. Right retrograde study shows multiple ureteric strictures and gross distortion of the internal architecture of the affected kidney.

content has a typical appearance on CT. Malignant elements are present in about one-quarter and may metastasise.

Malignant neoplasms

Renal neoplasm in children

Wilms' tumour (synonym: nephroblastoma)

This mixed tumour contains elements from embryonic nephrogenic tissue (Figure 75.38). Nephroblastoma is usually discovered during the first five years of life, usually in one pole of one kidney. Bilateral tumours pose a difficult problem.

Pathology

A rapidly growing tumour is likely to be friable in consistency.

Clinical features

An abdominal tumour grows rapidly in a poorly child. The mass may be very large. Some patients are hypertensive.

Haematuria is an unfavourable symptom denoting extension of the tumour into the renal pelvis.

Imaging confirms a solid space-occupying lesion in the kidney, with or without venous invasion, contralateral disease and distant spread.

Metastasis to the lungs occurs early. Liver, bone and brain metastases are rare. Lymphatic spread is uncommon.

Treatment

These children are best treated in specialist paediatric oncology units. Most unilateral tumours are treated by chemotherapy followed by nephrectomy. Partial nephrectomy may be possible in patients with bilateral disease.

Prognosis

Eighty per cent survive long term with modern chemotherapy and surgery. The prognosis is worse in those with metastases and in older children (Summary box 75.28).

Summary box 75.28

Nephroblastoma (Wilms' tumour)

- Usually presents in the first five years of life
- Typically presents with an abdominal mass
- May cause haematuria, abdominal pain or fever
- Metastasises to the lung
- Is best treated in a specialist paediatric oncology unit

Renal neoplasm in adults

Hypernephroma (synonym: Grawitz's tumour)

This adenocarcinoma, the most common neoplasm of the kidney (75 per cent incidence), arises from renal tubular cells.

Pathology

The cut surface is usually yellowish or dull white, semi-transparent, with areas of haemorrhage (Figure 75.39). The tumour is often divided into lobules, some of which are cystic. Larger tumours are irregular in shape with central haemorrhage and necrosis.

Microscopic structure

The most common pattern is of solid areas of polyhedral or cubical clear cells with deeply stained, small, rounded nuclei and abundant cytoplasm containing lipids, cholesterol and glycogen. The cells are occasionally arranged as papillary cysts or tubules. Less commonly, the cells are granular (dark), and both clear and dark cells may be represented in the same tumour. The scanty stroma is richly vascular.

Spread

The tumour is prone to grow into the renal vein. Cells enter the circulation and reach the lungs, where they grow to form can-

Figure 75.37 (a and b) Nephroureterectomy specimen from a patient with a kidney destroyed by tuberculous pyonephrosis.

Figure 75.38 Wilms' tumour.

nonball secondary deposits (Figure 75.40). Metastasis to bone also occurs and a secondary deposit in a long bone may be the only sign of distant spread for a year or more. Highly vascular metastases may pulsate. Tumour extending beyond the renal capsule is liable to metastasise via the lymph nodes in the hilum of the kidney to the para-aortic nodes and beyond.

Clinical features

Adenocarcinoma of the kidney is more common in men. Haematuria is usually the presenting symptom, sometimes with clot colic. There may be a dragging discomfort in the loin or the patient may detect a mass. In men, a rapidly developing

varicocele is a rare but impressive sign, most often on the left side because the left gonadal vein is obstructed where it joins the left renal vein.

Atypical presentations

In 25 per cent of cases there are no local symptoms. The patient presents with symptomatic secondary deposits in bone (Figure 75.41) or the lung (persistent cough or haemoptysis).

Occasionally, persistent pyrexia (37.8–38.9°C) with no evidence of infection is the only symptom. Pyrexia after nephrectomy suggests metastases.

A few patients present with constitutional symptoms and anaemia.

Polycythaemia occurs in 4 per cent of cases as a result of the production of erythropoietin by tumour cells. The erythrocyte sedimentation rate is always raised above the 1–2 mm found in idiopathic polycythaemia vera. The blood count returns to normal after nephrectomy unless there are metastases. Other hormones, such as renin and calcitonin, may be produced by the tumour. Hypercalcaemia is common.

Nephrotic syndrome has been reported as a rare presentation of hypernephroma.

Investigation

IVU is being supplanted by CT in the investigation of haematuria. There is typically abnormal calcification and distortion of the renal outline. The calyces may be stretched and distorted. It is important to know whether the contralateral kidney is working (Figure 75.42). CT with enhancement will demonstrate the extent of the lesion and will show whether the hilar lymph nodes or renal vein are involved (Figure 75.43).

Enthusiasm for renal angiography and preoperative embolisation has waned. Occasionally, a flush inferior cava shows the extent of caval involvement by tumour growing in from the renal vein.

A chest x-ray is essential to detect lung secondaries. An isotope bone scan will reveal deposits in bone.

Figure 75.39 Adenocarcinoma of the kidney (Grawitz's tumour).

Figure 75.40 Cannonball secondaries from a hypernephroma.

Treatment

Nephrectomy can be performed through a loin or a transverse or oblique upper abdominal incision. The transabdominal approach has the advantage that the renal pedicle and the inferior vena cava can be widely exposed.

The vascular pedicle should be ligated before the kidney is mobilised because handling the tumour may cause malignant cells to be released into the circulation. The first step in the procedure is to ligate the renal artery in continuity. Once the artery is occluded, the tumour loses most of its profuse blood supply and massive bleeding during mobilisation becomes less likely. Gentle palpation of the renal vein ensures that there is no tumour in its lumen. An empty vein can be divided between ligatures. The renal artery is then divided and the kidney mobilised within its coverings. Aberrant vessels feeding the tumour must be ligated or coagulated to avoid troublesome bleeding. The ureter is then traced downwards as far as is safe, tied and divided.

If the renal vein or the inferior vena cava is invaded, the surgeon must obtain early control of the cava above and below the tumour extension. If there is extension into the thorax, the cardiac team may be needed to put the patient on cardiac bypass so that tumour can, if necessary, be removed from the right side of the heart.

Renal adenocarcinoma responds poorly to radiotherapy or conventional chemotherapy. There have been early promising results from clinical trials of the cytokine interleukin-2 in this condition.

Prognosis

Removal of even a large neoplasm may be curative. In operable cases, 70 per cent of patients are well after three years and 60 per cent after five years. Macroscopic involvement of the renal vein or its tributaries, invasion beyond the capsule and lymphatic involvement all worsen the prognosis (Summary box 75.29).

Figure 75.41 Arteriogram showing a vascular 'blush' due to metastasis in the femur from a Grawitz's tumour.

Figure 75.42 Intravenous urogram in a case of hypernephroma of the left kidney. The only symptom was one attack of painless haematuria. Note the displacement of the upper pole calyces by the mass.

Figure 75.43 Computed tomography scan showing large bilateral renal adenocarcinomas.

Summary box 75.29**Adenocarcinoma of the kidney**

- Often presents with haematuria
- May be associated with pyrexia of unknown origin, polycythaemia, hypercalcaemia, anaemia and other paraneoplastic symptoms
- Metastases via the bloodstream to bone, liver and lung (cannonball secondaries)
- Renal vein extension may embolise to the pulmonary circulation during nephrectomy

Papillary transitional cell tumours of the renal pelvis

These resemble those of the bladder but are much less common (Figure 75.44). They may invade the renal parenchyma, be multifocal and metastasise. Multiple ureteric tumours are thought to arise from a field change that predisposes the whole urothelium to metaplasia rather than seeding down the ureter. Whether the carcinogen is chemical or viral is uncertain.

Clinical features

Haematuria is the most common clinical symptom.

The presence of malignant cells in the urine may indicate whether the tumour is well or poorly differentiated. There is some evidence that those with poorly differentiated tumours do better if they have preoperative radiotherapy. It is therefore useful to obtain cells from the tumour by sampling using a brush or catheter passed up the ureter under radiological control.

Intravenous urography usually demonstrates the tumour (Figure 75.45). Retrograde pyelography may be helpful if the urogram is indistinct.

Treatment

Conventional surgical treatment is by nephroureterectomy. The ureter must be disconnected with a cuff of bladder wall. If this is done by open surgery a second incision is needed to remove the kidney. Alternatively, the ureteric orifice can be widely resected

with a resectoscope and the ureter delivered by blunt dissection from the upper abdominal wound used to remove the kidney. Some urologists argue that well-differentiated upper urinary tract transitional tumours should be treated conservatively by resection with appropriate steps taken to avoid the growth of tumour seeded in the percutaneous track.

Squamous cell carcinoma of the renal pelvis

This is rare and often associated with chronic inflammation and leucoplakia resulting from stone. The tumours are radiosensitive but metastasise early and the prognosis is poor.

Transitional cell tumours of the ureter

These are rare and behave like tumours of the renal pelvis. Treatment is by nephroureterectomy.

About half of patients with tumours of the upper urinary tract will have tumours in the bladder at some stage. Follow up by cystoscopy with regular urography is therefore necessary to detect recurrent tumours.

Balkan nephropathy

Transitional cell tumours of the upper urinary tract have a very high incidence in certain areas of the Balkans. The same population has a high incidence of a form of primary nephropathy. The causative agent has not been identified with certainty but there seems to be an association with the consumption of grain products stored in a damp environment. Tumours that develop against a background of Balkan nephropathy should be treated by nephron-sparing surgery in view of the impaired overall renal function.

Figure 75.44 Papillary transitional cell tumour of the renal pelvis.

Figure 75.45 Intravenous urogram showing a filling defect in the left renal pelvis due to transitional cell carcinoma.

The Balkans are the countries of the southeast of Europe. They lie south of the Danube and Sava rivers, and form a peninsula bounded on the east by the Aegean and Black Seas, on the west by the Adriatic and Ionian Seas, and on the south by the Mediterranean.

Nephrectomy for benign disease

Nephrectomy is now rarely performed for benign disease except when the kidney is atrophic or dysplastic or the cause of accelerated hypertension. Non-functioning kidneys resulting from longstanding obstruction or stone disease are a potential site for infection and even malignancy. In a simple nephrectomy, the kidney is dissected free through the convenient plane between the capsule and its fatty coverings. If this plane is obscured by the scarring of previous surgery, a subcapsular nephrectomy may be safer.

Laparoscopic renal surgery

The benefits of laparoscopy are being progressively applied to the whole range of renal surgery. Laparoscopic nephrectomy is certainly possible for small kidneys destroyed by benign disease. The technique requires special skills and the full costs and benefits are under evaluation. More complex techniques are necessary when there is bulky excised tissue to be extracted. Laparoscopic surgery for pyeloplasty, ureterolysis and nephrectomy for renal malignancy have all been described.

Hypertension and a unilateral renal lesion

Ischaemia of the renal parenchyma leads to the release of pressor agents that cause arterial hypertension. When a renal lesion is discovered during the investigation of hypertension, nephrectomy may make the hypertension more amenable to drug treatment.

LEARNING OBJECTIVES

To understand:

- The anatomy, vascular supply and innervation of the bladder in relation to function and disease
- The principles of management of bladder trauma, incontinence and fistulae
- The common causes of acute and chronic urinary retention and management
- The different types of bladder cancer and the principles of management

SURGICAL ANATOMY OF THE BLADDER

- It is lined by transitional epithelium covering the connective tissue lamina propria, which contains a rich plexus of vessels and lymphatics.
- When the detrusor muscle hypertrophies, the inner layer, covered by urothelium, stands out, resulting in the appearance of trabeculation.
- Over the trigone is a thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and into the proximal urethra.
- Around the male bladder neck is the smooth muscle internal sphincter innervated by adrenergic fibres, which prevents retrograde ejaculation.
- The distal urethral sphincter is a horseshoe-shaped mass of striated muscle that lies anterior and distal to the prostate, or in the proximal two-thirds of the female urethra. It is distinct from the pelvic floor and is supplied by S2–S4 fibres via the pudendal nerve and by somatic fibres passing through the inferior hypogastric plexus.

Fascial and ligamentous supports of the bladder

At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy. The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the periosteum of the pubis and lie lateral to the dorsal vein complex. The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments. Condensations of fascia also occur around the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the

anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries (and from the uterine and vaginal arteries in females) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder. In the male, the prostatic plexus is continuous with the vesical plexus, which drains into the internal iliac vein. In the female, similar large veins are continuous with the vaginal plexus.

Lymphatics

These accompany the veins and drain to nodes along the internal iliac vessels and then to the obturator and external iliac chains. Some lymphatics pass to nodes that are situated posteriorly to the internal iliac artery (hypogastric nodes).

INNERVATION**The parasympathetic input**

This is derived from the anterior primary divisions of the second, third and fourth sacral segments (mainly S2 and S3). Fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from where they are distributed to the bladder (Figure 76.1). The pelvic plexus can be damaged during deep pelvic operations.

The sympathetic input

This arises in the 11th thoracic to the second lumbar segments; fibres pass via the presacral hypogastric nerve (rather than via the sympathetic chains) to the inferior hypogastric plexus.

Somatic innervation

A somatic innervation passes to the distal sphincter mechanism via the pudendal nerves and also via fibres that pass through the inferior hypogastric plexus.

Figure 76.1 The nervous control of the bladder. Micturition is partly a reflex and partly a voluntary act.

Functional aspects

Sympathetic nerves convey afferents from the fundus. Afferents arise from the mucosa, where they respond to touch, temperature and pain, and from the detrusor and lamina propria, where they convey stretch information. Afferents pass via the inferior hypogastric plexus to the posterior roots of S2–S4. Some aspects of micturition are centred in the pons, where detrusor contraction is coordinated with inhibition of the distal sphincter. Interruption of this pathway below the pons with preservation of the sacral cord is likely to result in a contractile detrusor and tonically active distal sphincter that will not relax during voiding (detrusor–sphincter dyssynergia).

Figure 76.2 Ectopia vesicae in a male. A drop of urine (arrow) is seen at the left ureteric orifice, the corona glandis being retracted by threads (courtesy of GD Adhia, Bombay, India).

CONGENITAL DEFECTS OF THE BLADDER

Bladder exstrophy

Clinical features

Bladder exstrophy occurs in 1:50 000 births (male–female ratio 4:1) (Figure 76.2). In the male, the penis is broad and short, and bilateral inguinal herniae may be present. There is separation of the pubic bones (Figure 76.3). In epispadias alone, the pubes are united and external genitalia are almost normal, although in the female the clitoris is bifid (Figure 76.4).

Treatment

The bladder is closed in the first year of life, usually following osteotomy of both iliac bones just lateral to the sacroiliac joints. Later, reconstruction of the bladder neck and sphincters is required. In some patients the reconstructed bladder remains small and requires augmentation. One-stage reconstruction is being practised in some major centres.

Less satisfactorily, urinary diversion can be carried out by means of ureterosigmoid anastomosis, an ileal or colonic conduit, or continent urinary diversion. Long-term complications include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) an increased (20-fold) risk of tumour formation (adenoma and adenocarcinoma) at the site of a ureterocolic anastomosis.

Figure 76.3 Separation of the pubes in a case of ectopia vesicae (courtesy of the late Professor Grey Turner, London, England).

Figure 76.4 Female epispadias showing deficient sphincter and bifid clitoris.

BLADDER TRAUMA

Bladder rupture

This can be intraperitoneal (20 per cent) or extraperitoneal (80 per cent) (Figures 76.5 and 76.6). Intraperitoneal rupture is usually secondary to a blow or fall on a distended bladder, more rarely to surgical damage. Extraperitoneal rupture is caused by blunt trauma or surgical damage. Gross haematuria can be absent. It may be difficult to distinguish extraperitoneal rupture from rupture of the membranous urethra (see Chapter 78). Intraperitoneal rupture is associated with sudden severe pain in the hypogastrium, often accompanied by syncope. The shock subsides and the abdomen distends and there is no desire to micturate. Peritonitis does not follow immediately if the urine is sterile; varying degrees of rigidity are present on examination.

Investigation

Computed tomography (CT) is ideal. Plain erect x-rays may show a ground-glass appearance (fluid). Intravenous urography (IVU) may confirm a leak. Retrograde cystography will confirm the diagnosis (Figure 76.7). It is important to image the patient after drainage of contrast as the full bladder may mask extravasation (Summary box 76.1).

Summary box 76.1

Bladder trauma

- Intraperitoneal or extraperitoneal
- Suspected if there is trauma and damage to the pelvis
- May be diagnosed by retrograde cystography

Figure 76.5 Intraperitoneal extravasation of urine.

Figure 76.6 Extraperitoneal extravasation of urine.

Figure 76.7 Cystogram of a patient who has fallen over and developed severe abdominal pain. Leakage of contrast into the peritoneal cavity is seen.

Treatment of intraperitoneal rupture

A lower midline laparotomy should be performed; the edges of the rent are trimmed and sutured with a single-layer 2/0 absorbable suture. A suprapubic and a urethral catheter are placed. Very rarely, the rupture will be through an unsuspected tumour; a biopsy can be taken before suturing the defect. Laparoscopic approaches are also now being used.

Injury to the bladder during operation

The bladder may be injured in: (1) inguinal or femoral herniotomy; (2) hysterectomy; and (3) excision of the rectum. If the injury is recognised, the bladder must be repaired and catheter drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental extraperitoneal perforation of the bladder occurs during endoscopic resection, drainage of the bladder with a urethral catheter and the administration of antibiotics usually suffice. If a mass of extravasated fluid is present it is best to place a small drain through a stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection (Summary box 76.2).

Summary box 76.2

Management of bladder trauma

- Extravesical injury – catheter drainage for 10 days
- Intraperitoneal injury – laparotomy, repair and bladder drainage

RETENTION OF URINE

Acute retention

There are many possible causes of acute retention of urine (see also Chapter 77) (Summary box 76.3).

Summary box 76.3

The most frequent causes of acute retention

Male

- Bladder outlet obstruction (the commonest cause)
- Urethral stricture
- Acute urethritis or prostatitis
- Phimosis

Female

- Retroverted gravid uterus
- Bladder neck obstruction (rare)

Both

- Blood clot
- Urethral calculus
- Rupture of the urethra
- Neurogenic (injury or disease of the spinal cord)
- Smooth muscle cell dysfunction associated with ageing
- Faecal impaction
- Anal pain (haemorrhoidectomy)
- Intensive postoperative analgesic treatment
- Some drugs
- Spinal anaesthesia

Clinical features

- No urine is passed for several hours.
- Pain is present.
- The bladder is visible, palpable, tender (Figure 76.8) and dull to percussion.
- Potential neurological causes should be excluded by checking reflexes in the lower limbs and perianal sensation.

Treatment

Treatment is to pass a fine urethral catheter (14F – French gauge is defined as the circumference in millimetres) and arrange urological management. Occasionally, in postoperative retention a warm bath can help (Figures 76.9, 76.10, 76.11 and 76.12).

Figure 76.8 Distended bladder in a man who presented with retention of urine.

Figure 76.9 Cleaning of the penis before catheterisation.

Figure 76.10 Insertion of local anaesthetic before insertion of a catheter.

Figure 76.11 The use of a penile clamp to ensure that sufficient time is given to allow the anaesthetic to work before the catheter is inserted.

Figure 76.12 A selection of silicone catheters.

Urethral catheterisation

Following a thorough hand wash, sterile gloves are donned. The genitalia are cleaned using soapy antiseptic. Lignocaine gel is inserted into the urethra, warning the patient that this may create stinging. The jelly should be massaged posteriorly in an attempt to anaesthetise the sphincter region, and it is of advantage to place a penile clamp for several minutes. A small Foley catheter should be passed while the penis is held taut. In a female patient, the labia should be parted using the middle and index fingers of the left hand, which should not be moved once cleaning has been performed. Providing a stricture is not the cause, the catheter should pass freely. Once urine begins to drain, it is wise to pass a few more centimetres of catheter into the bladder before the balloon is inflated to avoid inflation in the prostate. Force must not be used (Summary box 76.4).

Summary box 76.4

Catheterisation for acute retention of urine

Following catheterisation:

- Record the volume of urine drained
- Examine the abdomen to exclude other pathology (rupture of an aortic aneurysm, ureteric colic or diverticulitis can cause confusion)

If the catheter will not pass, it is usually due to poor technique, lack of anaesthesia, traumatising of the urethra or a urethral stricture. Occasionally, a large prostatic middle lobe may prevent the catheter entering the bladder; sometimes a coude catheter will pass. If a catheter cannot be passed the following plan should be pursued.

Suprapubic puncture

Suprapubic puncture with commercially available catheters such as Cystofix or Lawrence Add-a-Cath catheters is straightforward provided that the bladder is palpable. The skin, fascia and retropubicspace are anaesthetised with 0.5 per cent lignocaine. Correct placement is confirmed by aspiration. A large-bore needle is then placed into the bladder, down which a fine catheter is passed (Cystofix) and then secured in position. The other option is to place a plastic suprapubic trocar and cannula, which has a removable plastic strip on the side. A standard 12F Foley catheter can be passed down the cannula, the balloon is inflated, the cannula is extracted and the strip is pulled away from the catheter (Add-a-Cath). If urine cannot be aspirated through the fine-bore needle, passing a suprapubic trocar should

not be attempted.

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic.

Urethral instrumentation

In a patient with a known stricture, an experienced urologist may elect to dilate the stricture or to take the patient to theatre to carry out an optical urethrotomy (see Chapter 78).

Chronic retention

In chronic retention there is no pain. These patients are at risk of upper tract dilatation because of high intravesical tension – they require urgent urological referral. Men with impaired renal function may develop post-obstructive diuresis following catheterisation. Such men need careful monitoring, with replacement of inappropriate urinary losses by intravenous saline; they are also at risk of haematuria as the distended urinary tract empties. Often it is several days before full renal recovery occurs.

Retention with overflow

The patient is incontinent with small amounts of urine passing involuntarily from the distended bladder. It usually follows a neglected retention.

Indwelling catheters and closed systems of catheter drainage

The risk of ascending infection is decreased by connecting the catheter to sterile tubing connected to a collecting bag. Irrigations should be avoided unless clot retention occurs. When a catheter has been *in situ* for a few days, some degree of urethritis and bacteriuria is likely; changing a catheter then entails risks of severe infection if prophylactic antibiotics are not used (Figure 76.13).

Acute retention due to drugs

A number of drugs can induce retention, including antihistamines, anti-hypertensives, anti-cholinergics and tricyclic antidepressants.

Figure 76.13 Modern Simpla bag used for continuous bladder drainage. (The nurse who is emptying the bag should be wearing disposable gloves to avoid contaminating the hands with organisms.)

The acute neuropathic bladder

- 1 Immediately after spinal cord injury, 'spinal shock' occurs (see Chapter 35), which may last for days or months. The detrusor is not able to contract, the bladder distends and overflow incontinence occurs. Neglected bladder distension will lead to damage to the detrusor, infection and ultimately renal failure. Management is as follows:
- 2 The bladder must be emptied by aseptic intermittent catheterisation performed two or three times daily or the use of an indwelling urethral catheter on continuous drainage, making sure that the patient has a high urinary output (3 litres per day) to combat infection. Currently, intermittent catheterisation is preferred as soon as the patient's spinal injury is stable.
- 3 Neurological examination must be performed to assess the level of sensory and motor loss. Ischaemic necrosis of the cord may extend below the upper level of cord injury. When sensory loss below the upper level is total, recovery is unlikely. Incomplete lesions may recover somatic and bladder function.
- 4 Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact and that reflex bladder contractions are likely to develop, though they may be insufficient to empty the bladder. If there is persistent total loss of reflexes and perineal sensation then either the sacral cord or cauda equina is damaged. In such circumstances, an acontractile bladder is likely. In cauda equina lesions, there may be sensory, motor or mixed loss.
- 5 Full urodynamic assessment of bladder function should be undertaken when the injury is stable. This allows an accurate assessment of bladder and sphincter activity and will enable decisions to be made about further management; the prime aim is to prevent upper tract damage by promoting good bladder emptying (Summary box 76.5).

Summary box 76.5

Clinical management of spinal injury

- The bladder should be emptied during spinal shock by catheterisation
- Encourage high fluid intake
- Commence intermittent catheterisation
- When the patient is stable, undertake full urodynamic evaluation

The following situations represent the typical patterns of bladder function seen after spinal cord injury.

Lesions above T10

Usually leads to an 'upper motor neurone' bladder with reflexes intact but isolated from higher control mechanisms. Such patients are at risk of autonomic dysreflexia.

Because of detrusor-sphincter dyssynergia, bladder contractions are high pressure and ineffective in producing bladder emptying; the bladder neck is normally open. If left untreated, upper tract dilatation and renal failure may result. Bladder capacity is usually decreased with the development of trabeculation and a typical 'fir-tree' appearance. Patients are incontinent during high-pressure phasic contractions because the sphincter resistance suddenly diminishes.

Some patients with low-pressure bladders that empty may be managed by means of condom drainage. Others will require clean intermittent self-catheterisation (CISC), popularised by Lapides. Patients with poor emptying, low bladder capacity and upper tract dilatation require treatment with endoscopic sphincterotomy and condom drainage. Some carefully selected patients may require bladder reconstruction.

Lesions involving the sympathetic outflow (T11, T12, L1, L2)

These patients are usually similar to the group with lesions above T10.

Damage to the sacral centre S2, S3, S4 and cauda equina lesions

Usually leads to a 'lower motor neurone' bladder, also found in spina bifida (myelodysplasia); the detrusor is acontractile. Abdominal straining can produce reasonable emptying but the mainstay is CISC. Some patients may have sensation of filling through the hypogastric nerves, if T11 and T12 are intact. The bladder capacity may be good, but some patients have high resting pressures and high increases during bladder filling, which means that there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed but of fixed resistance. Vesicoureteric reflux is common and upper tract damage is frequent in neglected cases. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Bladder dysfunction after excision of the rectum or radical hysterectomy

Between 10 and 15 per cent of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus, leading to impotence in the male and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion. Postoperative retention in other patients may also be caused by simple bladder outlet obstruction. The best plan is to catheterise the patient to allow postoperative recovery and then carry out urodynamic investigation to determine the appropriate treatment.

INCONTINENCE OF URINE

Overall, urinary incontinence occurs in 5 per cent of men and 20 per cent of women. Up to 40 per cent of women over the age of 60 years and 50 per cent of institutionalised elderly patients experience regular episodes of urinary incontinence. Health problems include skin breakdown and depression, and loss of esteem and sexual activity. Continence is dependent on normal mobility and brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism, which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying, and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence. In children, non-neurogenic incontinence is often associated with other dysfunctional conditions such as infections, constipation, psychological factors, increased fluid intake, intentional misconduct or an

overactive bladder. Several investigations are required for diagnosis of urinary incontinence (Summary box 76.6).

Summary box 76.6

Diagnosis of urinary incontinence

The following investigations are required:

- A careful history and physical examination and completion of frequency voiding charts
- Urodynamic testing in most patients and in all patients in whom surgical intervention is proposed
- Urine culture to exclude infection and measurement of serum creatinine

In selected cases, IVU is carried out if a ureteric fistula is suspected, although ultrasound examination will often provide adequate details.

Urodynamic testing

The key to the practical management of lower urinary tract dysfunction, and particularly incontinence, lies with urodynamic investigation. The principle is to artificially simulate bladder filling and emptying while obtaining pressure measurements (Figure 76.14).

The patient attends with a full bladder and is allowed to void in private to measure the maximum urinary flow rate. After voiding, the residual urine is measured by ultrasound. A pair of catheters or a twin-lumen catheter is passed into the bladder, which allows the bladder to be filled at a rate of 50 mL/min while a continuous recording of intravesical pressure is made. To obtain 'true' detrusor pressure, a second channel is required to assess intra-abdominal pressure, measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that the bladder is full. X-ray screening may be carried out to assess bladder neck closure and urinary leakage during movement or coughing (stress incontinence) or during bouts of phasic detrusor pressure (detrusor instability). The patient is

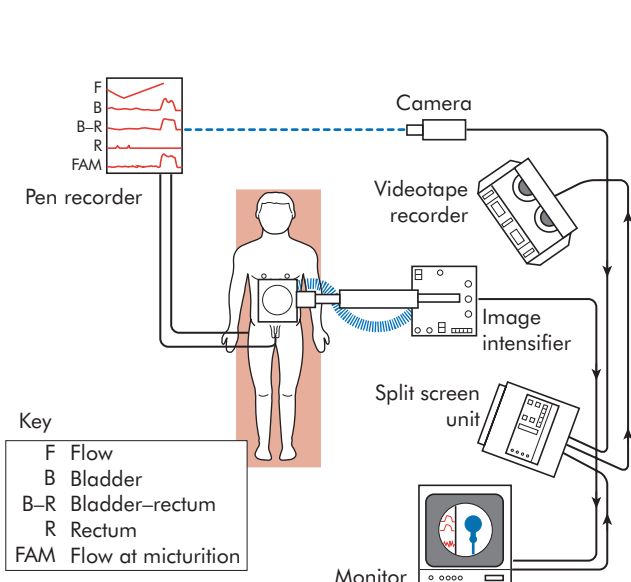

Figure 76.14 Urodynamic study.

then asked to void at the end of bladder filling after the filling catheter has been removed (Figure 76.15).

The normal bladder will accept approximately 400–550 mL when filled at room temperature at a rate of <50 mL/min. The pressure increase in the bladder should be less than 15 cmH₂O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH₂O in men and about 40 cmH₂O in women, with a flow rate of between 20 and 25 mL/s.

Common abnormalities identified during urodynamic testing in incontinence

The overactive bladder

Phasic increases in pressure give rise to urgency and urge incontinence (detrusor overactivity; Figure 76.16). This abnormality is found in patients with neurogenic bladder dysfunction, such as in multiple sclerosis (MS) or Parkinson's disease or following a stroke or spinal injury, when it is known as detrusor hyperreflexia. About 50 per cent of men with bladder outflow obstruction have detrusor instability, and in about half of them the instability resolves after prostatectomy. Idiopathic detrusor overactivity is common and must be distinguished from genuine stress incontinence (GSI) in women before performing bladder neck suspension procedures. In children, overactive bladder symptoms must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

Genuine stress incontinence

This is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not to increased true detrusor pressure (see Figure 76.15). It is caused by sphincter weakness.

Chronic urinary retention

Chronic urinary retention with overflow incontinence is recognised by a large residual volume of urine (Figure 76.17) and is usually associated with high pressures during bladder filling.

Figure 76.15 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy, which records urinary leakage. A cough is shown, which results in genuine stress incontinence.

Figure 76.16 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy which records urinary leakage. Phasic activity is shown, which is detrusor instability resulting in urge incontinence.

Bladder outflow obstruction

Bladder outflow obstruction is associated with increased voiding pressures, often in excess of 90 cmH₂O (Figure 76.18), coupled with low urinary flow rates.

Neurogenic dysfunction

Neurogenic bladder dysfunction may also be identified (Summary box 76.7).

Summary box 76.7

Uses of urodynamic testing

- To distinguish GSI (due to sphincter weakness) from detrusor instability in women (see Figure 76.15)
- For the classification of neurogenic bladder dysfunction
- To distinguish bladder outflow obstruction from idiopathic detrusor instability in men
- To investigate incontinence or other lower urinary tract symptoms

Causes of incontinence

There are various ways of classifying the causes of incontinence.

- **Problems of social control.** Patients with dementia often have incontinence because of uninhibited detrusor hyperreflexia and impaired social perception.
- **Storage problems.** Patients with a small bladder capacity owing to fibrosis (tuberculosis, radiotherapy or interstitial cystitis) can develop incontinence. Patients with a small functional capacity owing to severe detrusor instability, neurogenic dysfunction or infection can develop incontinence.
- **Impairment of emptying.** Patients with chronic retention or neurogenic bladder dysfunction have small functional bladder

Figure 76.17 An ultrasound scan showing a large post-void residual urine.

capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.

- **Weak sphincter.** This leads to GSI and can follow surgical procedures such as radical prostatectomy in men.
- **Fistulae.** Leakage from fistulae or upper tract duplication with an ectopic ureter.
- **In children,** the causes must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

The common causes may be classified into male, female or mixed-sex groups.

Male incontinence

Chronic urinary retention with overflow

This may be due to benign prostatic hypertrophy, carcinoma

Figure 76.18 A conventional urodynamic trace showing detrusor pressure during voiding. There has been a change of scale because the pressure was so high; voiding pressures are increased with a low flow rate, which is diagnostic of bladder outflow obstruction.

of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. Examination may reveal that the bladder is distended, and it can be confirmed by ultrasound scanning. The treatment is discussed in Chapter 77.

Post-prostatectomy

Post-prostatectomy incontinence may result from injury to the external sphincter mechanism. Treatment should be conservative initially with pelvic floor exercises, and an anastomotic stricture must be excluded. The condition may necessitate insertion of an artificial urethral sphincter (Figure 76.19).

Female incontinence

Stress incontinence

The most common cause is GSI, although in some parts of the world, vesicourethral fistulae as a result of neglected labour are common. It is usually found in multiparous women with a history of difficult labour. It can be found in normal young women who indulge in competitive trampolining and in patients with epispadias. The classical symptom is urine loss during coughing, laughing, sneezing or a sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test, which is performed by putting the patient through a standard set of tests with 300 mL of fluid in the bladder; in GSI the fluid losses usually range from 10 to 50 mL. Urinary frequency and urgency are often found in such patients as they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can mimic GSI and coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, as the outcome of surgery is suboptimal in women with idiopathic detrusor instability.

Minor to moderate stress urinary incontinence can be controlled by pelvic floor exercises. However, if this fails, surgery is indicated. Standard operations include open colposuspension or the use of a minimally invasive approach involving the insertion of a transvaginal tape (TVT procedure).

Open colposuspension

This operation is carried out through a Pfannenstiel incision with the patient in the Lloyd-Davies position. The vaginal fascia is identified by sweeping the bladder off the vagina and three sutures are placed on each side between the vaginal fascia and the iliopubic ligament. A suprapubic catheter is placed. Voiding difficulties are frequent but usually temporary. It is best to warn women with large bladder capacities and low voiding pressures that this complication may occur and that they may be required to carry out CISC for a period. The operation is very successful for the treatment of GSI, with good results at one year in 90 per cent of patients, which are maintained in about 80 per cent of patients at five years.

Modifications of bladder neck suspension can also be achieved by minimally invasive approaches such as the transvaginal sling. This technique does reduce both hospital stay and postoperative morbidity.

Incontinence common to both sexes

Idiopathic detrusor overactivity

Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in neurogenic bladder dysfunction (when it is known as detru-

sor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor overactivity may be symptomless but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis) depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction before surgical treatment. Infection, tuberculosis or carcinoma *in situ* (CIS) should be excluded. The mainstay of treatment is the use of various anti-cholinergic medications (oxybutynin and tolterodine). Severe symptoms resistant to conventional conservative treatment resulting in major impairment of quality of life may need more aggressive treatment, such as enterocystoplasty or the injection of small doses of botulinum toxin (the toxin from *Clostridium botulinum*), known as BoTox, which blocks cholinergic neuromuscular transmission, at least for a time.

Ageing

Ageing can result in smooth muscle cell dysfunction, which can cause combinations of small functional capacity, detrusor overactivity, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

Congenital

Congenital causes include ectopic vesicae and severe epispadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female patient should theoretically result in total urinary incontinence. This is discussed in Chapters 6 and 75.

Trauma

Trauma, whether from pelvic surgery or associated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra, or in fistula formation.

Infection

Lower urinary tract infection (UTI) may be sufficient to induce urinary incontinence. A history of frequency, burning and a fever should prompt the diagnosis. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

Figure 76.19 The artificial urinary sphincter made by American Medical Systems.

Neoplasia

Locally advanced cancers in the pelvis, particularly carcinoma of the cervix in a woman and carcinoma of the prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes

Constant dribbling of urine coupled with normal micturition

This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females or into the vagina. The history is diagnostic, and intravenous pyelography or ultrasound scanning may reveal the upper pole segment, which is often poorly functioning. Treatment is by excision of the aberrant ureter and portion of kidney. A ureteric fistula can be difficult to diagnose and its demonstration may require retrograde ureterography and a high degree of suspicion.

Nocturnal enuresis

This is a condition of young children and young adults. Of course, the time at which children become dry at night varies and, in some, nocturnal enuresis is merely a delayed onset of continence. In others, it persists until late adolescence and is classified into primary and secondary nocturnal enuresis. In children, once neurogenic dysfunction has been excluded, the condition can be associated with other symptoms such as intentional misconduct, infections, constipation and increased fluid intake. These causes must be ruled out before medication is considered.

Primary nocturnal enuresis occurs in patients with nocturnal symptoms alone, which are absent during the day. Often, they have been dry for a period, and the vast majority of patients will eventually become dry. In the meantime, a sympathetic approach to these children is essential. They often respond to a system of rewards using a 'star' chart. In addition, the use of DDAVP (a vasopressin analogue) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of an alarm that wakes the child (or at least the child's parents) when incontinence occurs and medication in the form of an anticholinergic drug such as oxybutynin.

Treatments for incontinence

Treatments are listed below. Management is dependent on making a correct diagnosis.

Management and treatment

Following careful assessment and investigation, many cases of incontinence can improve with simple measures such as lifestyle interventions, pelvic floor exercises with biofeedback, bladder training and incontinence devices where necessary. In mixed urge and stress incontinence, the major component has to be treated first.

Problems of social functioning

Patients with dementia may respond to regular toileting. Anticholinergic agents can cause increased confusion in these

patients and often, in severe cases, an indwelling catheter is needed.

Storage problems

Patients with a small bladder capacity because of fibrosis may require augmentation cystoplasty. Detrusor overactivity will require treatment with anti-cholinergic medication but, in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supratrigonal cystectomy followed by the need for detubularised ileocaecal segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should be carried out only after careful assessment in units used to dealing with such problems. Patients with very impaired mobility and MS may require ileal conduit diversion. The use of intravesical injections of BoTox has provided good improvements, and it may avoid or delay the need for major surgery.

Impaired bladder emptying

Patients with overflow incontinence because of bladder outflow obstruction will usually respond well to prostatectomy. Patients with impaired bladder emptying because of neurogenic bladder dysfunction should be treated in the first place by means of CISC.

Weak sphincter

Patients with GSI should be treated by means of pelvic floor exercises initially. Duloxetine can be used as medical treatment for GSI. Bulking agents, such as macropastique, can be used and can provide good temporary solutions. Surgical treatment by means of colposuspension or TVT may be needed. Those with post-prostatectomy incontinence or neurogenic bladder dysfunction may need to be fitted with an artificial urinary sphincter (Figure 76.19), if they are well motivated and mobile, but careful assessment is required.

Use of appliances

An indwelling catheter drained constantly into a leg urinal may be a satisfactory solution although, in some instances, diversion via an ileal conduit is necessary. In men, a condom urinary appliance may be satisfactory and can avoid an indwelling catheter.

More major surgical treatments

Various types of urinary diversion

Urinary diversion may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

Bladder substitution procedures

The principle behind these operations is the creation of a low pressure, large-capacity reservoir, which can be made using any segment of bowel isolated on its vascular pedicle (Figures 76.20, 76.21 and 76.22). This is then detubularised by dividing its anti-mesenteric border and suturing this into a plate, which is then reconfigured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be reimplanted into the bowel segment. This new bladder will need to be emptied by means of CISC in up to 30 per cent of cases.

'Clam' enterocystoplasty

This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It has been used in the treatment of idiopathic detrusor instability (Figure 76.23). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable bladder capacity (approximately 300 mL).

Fitment of artificial urinary sphincter

See Figure 76.19.

Summary

Treatments for incontinence can be summarised as follows:

- 1 Conservative measures such as lifestyle interventions, pelvic floor muscle and bladder training.
- 2 Devices for collection: external penile condom, or an indwelling urethral or suprapubic catheter.
- 3 Drugs: to decrease the strength of the bladder neck (e.g. adrenergic blockers); with mixed action on the bladder neck and central nervous system (e.g. tricyclic drugs); to inhibit bladder activity (e.g. anti-cholinergic drugs). Botulinum toxin A is used in selected patients. Duloxetine can be used as

medical treatment for GSI – it is a serotonin–noradrenaline (norepinephrine) reuptake inhibitor.

- 4 Intermittent self-catheterisation: to improve emptying.
- 5 Increasing outlet: pelvic floor physiotherapy; resistance colposuspension or TVT tapes or slings; periurethral injections of 'bulking agents' such as cross-linked collagen or other particles; use of the artificial urinary sphincter.
- 6 Denervation of bladder: S3 sacral nerve blockade, neurectomy or surgical transection of the bladder to inhibit bladder activity and improve functional capacity. These are rarely used nowadays because of the use of botulinum toxin and the clam cystoplasty or S3 nerve stimulation (see point 7).
- 7 Sacral nerve stimulation devices can improve incontinence. They involve percutaneous insertion of electrodes through the sacral foramina under radiological control and implantation of an electronic stimulator.
- 8 Augmentation of bladder: 'clam' enterocystoplasty, bladder capacity substitution with detubularised bowel segment.
- 9 Urinary diversion: ileal conduit, continent urinary diversion.

BLADDER STONES

Definition

A primary bladder stone is one that develops in sterile urine; it often originates in the kidney. A secondary stone occurs in the presence of infection, outflow obstruction, impaired bladder emptying or a foreign body.

Incidence

Until the twentieth century, bladder stone was a prevalent disorder among poor children and adolescents. Because of improved diet, especially an increased protein-carbohydrate ratio, primary vesical calculus is rare.

Composition and cystoscopic appearance

Most vesical calculi are mixed. An oxalate calculus is a primary calculus that grows slowly; usually, it is of moderate size and solitary, and its surface is uneven (Figure 76.24). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment. Uric acid calculi are round or oval, smooth and vary in colour from yellow to brown (Figure 76.25). They occur in patients with gout but are also found in patients with ileostomies or with bladder outflow obstruction. A cystine calculus occurs only in the presence of cystinuria and is radio-opaque because of its high sulphur content. A triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected

with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the other types of calculus; more rarely it occurs on a foreign body (Figures 76.26 and 76.27). It is dirty white in colour and of chalky consistency.

A bladder stone is usually free to move in the bladder and it gravitates to the lowest part of the bladder. Less commonly, the stone is wholly or partially in a diverticulum, where it may be hidden from view.

Clinical features

Men are affected eight times more frequently than women. Stones may be asymptomatic and found incidentally.

Symptoms

Frequency is the earliest symptom and there may be a sensation of incomplete bladder emptying. Pain (strangury) is most often found in patients with a spiculated oxalate calculus. It occurs at the end of micturition and is referred to the tip of the penis or to the labia majora; more rarely, it is referred to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of bladder stone. Haematuria is characterised by the passage of a few drops of bright-red blood at the end of micturition, and is due to the stone abrading the vascular trigone. Interruption of the urinary stream is due to the stone blocking the internal meatus. Urinary infection is a common presenting symptom.

Figure 76.25 Smooth uric acid-type stones.

Figure 76.26 Stone on a vaginal sling that had eroded into the bladder.

Figure 76.27 Uric acid stones that had formed on metal staples used to construct a colonic bladder augmentation.

Examination

Rectal or vaginal examination is normal; occasionally, a large calculus is palpable in the female. Examination of the urine reveals microscopic haematuria, pus or crystals that are typical of the calculus, for example envelope-like in the case of an oxalate stone or hexagonal plates in the case of cystine calculi. In most patients, the stone is visible on ultrasound or on a plain x-ray (Figure 76.28). Imaging of the whole of the urinary tract should be undertaken to exclude an upper tract stone. Nearly all stones can be dealt with endoscopically. In men with bladder outflow obstruction, endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment

The cause of the stone should be sought and treated; this may include bladder outflow obstruction or incomplete bladder emptying in patients with neurogenic bladder dysfunction.

Figure 76.28 Radiograph showing a vesical calculus (no contrast has been used).

Figure 76.29 'Blind' lithotrite used to crush bladder stones.

Litholapaxy

The blind lithotrite (Figure 76.29) was an early type of minimally invasive technique. Standard management now includes the optical lithotrite, electrohydraulic lithotrite, Holmium laser or ultrasound probe (Figure 76.30). Other devices include the stone punch, which is useful to crush small fragments further so that they can be evacuated with an Ellik evacuator. Contraindications to perurethral litholapaxy are extremely rare:

- urethral: a urethral stricture that cannot be dilated sufficiently; when a patient is aged below ten years;
- bladder: a contracted bladder;
- stone characteristics: a very large stone.

Ultrasound lithotripsy is extremely safe but appropriate only for small stones. Laser lithotripsy with the holmium laser can deal with most large stones. Once small fragments are produced, the optical lithotrite can be used to finish the job. For evacuation of the fragments, fluid (200 mL) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand; the returning solution carries with it fragments of stone.

Milo Ellik, b. 1905, American urologist. One of the original members of the Los Angeles Urological Society. In 1932 Dr Alcock, a pioneer of transurethral resection of prostate, persuaded one of his residents, Milo Ellik, to go to the Chemistry Department glass blowing shop where he devised his evacuator. Unfortunately he never had a patent on his device which was patented by Bard, the surgical company, in the 1940s.

Figure 76.30 An endoscopic ultrasound probe, which is used to fragment bladder or kidney stones.

Percutaneous suprapubic litholapaxy

It is possible to insert a needle into the bladder and then pass a guidewire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track and an Amplatz sheath inserted followed by a large-bore nephroscope. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

Removal of a retained Foley catheter

A retained Foley catheter is usually caused by the channel that connects the balloon to the side arm becoming blocked, usually at the end near the balloon. The best way of dealing with this problem is to further inflate the balloon with 20 mL of water and then burst the balloon percutaneously using a needle under ultrasound screening. If the balloon bursts, it is important to subsequently cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus. Cutting off the side arm and attempting to clear the channel with a wire is only occasionally successful.

FOREIGN BODIES IN THE BLADDER

The most common foreign body in the bladder is a fragment of catheter balloon (see above). Occasionally, a foreign body enters through the wall of the bladder, for example non-absorbable sutures used in an extravesical pelvic operation. Complications include:

- lower UTI;
- perforation of the bladder wall;
- bladder stone.

Treatment

A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.

DIVERTICULAE OF THE BLADDER

Definition

The normal intravesical pressure during voiding is about 35–50 cmH₂O; however, pressures as great as 150 cmH₂O

Figure 76.31 Cystogram showing a large diverticulum of the bladder.

may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If one or more, but usually one, saccule is forced through the bladder wall, it becomes a diverticulum (Figure 76.31). Congenital diverticula are the result of a developmental defect.

Aetiology of diverticulae

Congenital diverticulae

These are situated in the midline anterosuperiorly and represent the unobliterated vesical end of the urachus.

Pulsion diverticula

The usual cause is bladder outflow obstruction.

Pathology

The mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 to 5 cm, but they may be larger. Diverticula are lined by bladder mucosa and the wall is composed of fibrous tissue only (compare with a traction diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter – probably because of peridiverticular inflammation.

Complications

Recurrent urinary infection

As the pouch cannot empty itself efficiently, there remains a stagnant pool of urine within it. Peridiverticulitis can cause dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leukoplakia are infrequent complications.

Bladder stone

This develops as a result of stagnation and infection. The stone often protrudes into the bladder.

Hydronephrosis and hydroureter

This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

Neoplasm

Neoplasm arising in a diverticulum is an uncommon complication (<5 per cent). The prognosis is dependent on the stage of the tumour (see below).

Clinical features

An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95 per cent) and over 50 years of age. Symptoms are those of associated urinary tract obstruction, recurrent infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30 per cent. In a few patients micturition occurs twice in rapid succession (the second act may follow a change of posture).

Diagnosis

Diverticula are usually discovered incidentally on cystoscopy or ultrasound (Figures 76.32, 76.33 and 76.34).

Indications for operation

Operation is necessary only for the treatment of complications. Provided the diverticulum is small and associated outflow obstruction has been dealt with by prostate resection, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

Combined intravesical and extravesical diverticulectomy

A ureteric stent is passed up the ureter on the affected side and the anterior bladder wall is exposed through a suprapubic incision. The bladder is incised in the midline and the diverticulum is packed with a strip of gauze. The neck of the diverticulum is separated from the ureter and, when the pouch is free, it is severed from the bladder. The resulting defect is closed in a single layer with 2/0 absorbable sutures. A suprapubic catheter is left in place and an extravesical drain is inserted. An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then

to detach the diverticulum together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain placed into it for 2–3 days. The track fibroses rapidly after removal of the drain. If bladder outlet obstruction is present, prostatectomy should be carried out at the same time as the diverticulectomy, using any appropriate method (transurethral resection of the prostate (TURP), laser or open) (Summary box 76.8).

Summary box 76.8

Bladder diverticula

- Bladder diverticula are most frequently diagnosed incidentally by cystoscopy or urinary tract imaging
- The presence of a diverticulum – even quite a large one – is not an indication for diverticulectomy unless symptoms or cancer are present

Figure 76.33 Occasional appearance of a diverticulum with inadequate distension of the bladder.

Figure 76.32 Cystoscopic appearance of the orifice of a diverticulum and trabeculation of the bladder.

Figure 76.34 Bladder diverticulum demonstrated by ultrasound.

Traction diverticulum (synonym: hernia of the bladder)

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5 per cent of such herniae treated by operation (Figure 76.35).

URINARY FISTULAE

Congenital urinary fistulae

The causes of congenital urinary fistulae include:

- ectopia vesicae;
- a patent urachus – the presence of a urinary leak from the umbilicus, present at birth or commencing soon after, suggests this diagnosis. In adult life, infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (Figures 76.36 and 76.37). Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded;
- in association with imperforate anus (see Chapters 8 and 73).

Traumatic urinary fistulae

Perforating wounds, damage not recognised during surgery or poor healing and avascular necrosis following radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after an open bladder operation may lead to dehiscence of the wound and a fistula, which will heal quickly provided the bladder is kept empty with an indwelling catheter.

Figure 76.35 (a) Intraperitoneal, (b) paraperitoneal and (c) extraperitoneal hernia of the bladder, in relation to a hernial sac.

Figure 76.36 An operative photograph showing a large urachal cyst in which adenocarcinoma formation has occurred. A partial cystectomy with total removal of the urachal remnant is about to be carried out.

Vesicovaginal fistulae

Aetiology

- **Obstetric.** The usual cause is protracted or neglected labour.
- **Gynaecological.** The operations chiefly causing this complication are total hysterectomy and anterior colporrhaphy.
- **Radiotherapy.**
- **Direct neoplastic infiltration.** Exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to implicate the bladder.

When an injury to the bladder is recognised and repaired, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulae are the result of ischaemic necrosis of the bladder because of prolonged pressure of the fetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in an artery forceps, including the bladder wall in a suture or perhaps even by local oedema or haematoma. Leakage because of necrosis of tissue seldom manifests itself before 7 days after the operation. An intractable fistula following radiotherapy for carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

Figure 76.37 A computed tomography scan of the same patient as in Figure 76.36, showing a large urachal cyst closely approximated to the dome of the bladder.

Clinical features

There is leakage of urine from the vagina and excoriation of the vulva. Vaginal examination may reveal a localised thickening on its anterior wall or in the vault. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall.

The 'three-swab test'

The differential diagnosis between a ureterovaginal and vesicovaginal fistula can be made by placing a swab in the vagina and injecting a solution of methylene blue through the urethra; the vaginal swab becomes coloured blue if a vesicovaginal fistula is present. Cystoscopy and bilateral retrograde ureterography provide a more reliable demonstration. An IVU should be performed to exclude a coincidental ureterovaginal fistula (ureterovaginal fistula occurs with vesicovaginal fistula in about 10 per cent of cases). Usually, the IVU shows some upper tract dilatation resulting from partial obstruction.

Treatment

Just occasionally, conservative management of a vesicovaginal fistula following hysterectomy, by urethral bladder drainage, is successful; however, the majority of fistulae will require definitive surgical repair. A low fistula (subtrigonal) is best repaired per vaginam. The fistula is exposed, the bladder is closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left *in situ* for at least 10 days. For higher (supratrigonal) fistulae, a transvaginal approach can be difficult. These patients should always be cystoscoped before the repair procedure and bilateral ureterograms performed. For high fistulae, a suprapubic approach is the best method in most hands; however, some experts will aim to carry out vaginal closure in most cases that have not involved complex surgery or radiotherapy.

To repair a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered, but the ureter can usually be found above the level of the injury and followed down. Reimplantation into the bladder is often required. Depending on the amount of ureter lost, it may be possible to achieve reimplantation with a psoas hitch procedure. If the gap is too large, a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric reimplantation is that there should be no tension on the repair.

Fistulae from renal pelvis to skin or gut

Tuberculosis of a kidney may result in a fistula to the duodenum, colon or skin. Similarly, a pyonephrosis may discharge into the gut or onto the skin. Duodenal ulcer involving the pelvis of the right kidney, Crohn's disease involving the renal pelvis or ureter, or cases of xanthogranulomatous pyelonephritis may cause fistulae. A longstanding urinoma will occasionally fistulate into the gut.

Fistulae arising from infection

The most common cause is diverticulitis of the colon. Fistulae may also follow Crohn's disease, appendix abscess or pelvis sepsis after acute salpingitis, or pelvic surgery.

The onset of a fistula from diverticular disease may well be

Figure 76.38 Cystoscopic view of a vesicointestinal fistula. Bubbles of gas can be seen issuing from the orifice of the fistula.

treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (Figure 76.38). A cystogram may reveal the fistula. The passage of gas per urethram in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

Treatment of fistulae caused by diverticular disease

In most patients a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; it is most important to ensure that the left colon and, if necessary, the splenic flexure are fully mobilised to facilitate a tension-free, well-vascularised anastomosis. The bladder is drained by a urethral catheter.

Fistulae caused by carcinoma

By the time that a fistula between the bowel and the bladder has developed, the tumour is usually locally advanced but may be operable.

Urethral fistulae in the male

These occur as the result of infection above a stricture producing a paraurethral abscess that ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of the thigh and lower abdominal wall. Widespread cellulitis and tissue necrosis (which may lead to Fournier's gangrene) may occur unless drainage of urine is achieved by suprapubic cystostomy and the tissue planes are freely drained by inguinal and scrotal incisions.

Neoplastic fistulae

Primary bladder tumours very rarely produce fistulae. Involvement of the bladder by tumours of the cervix, uterus, colon and rectum can produce fistulae, as may sarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment is difficult and in most cases only palliative

relief can be given. It is rarely in the patient's interest to carry out urinary diversion, although minimally invasive techniques, such as placement of ureteric stents, can be helpful in palliating symptoms (Summary box 76.9).

Summary box 76.9

Fistulae

- A fistula is a communication between two epithelium-lined surfaces
- Most urinary fistulae are vesicovaginal and result from obstetric trauma; an associated ureterovaginal fistulae occurs in about 10 per cent of cases
- A 'three-swab test' is used to aid the diagnosis. An examination under anaesthesia, vaginoscopy, and cystoscopy and IVU should be performed and, if necessary, retrograde ureterography
- Conservative management is rarely successful
- The principles of repair include good exposure, excision of diseased tissue and tension-free vascularised repair in anatomic layers
- Fistulae caused by radiation, cancer and sepsis can be complex with multiple tracts
- The persistence of a fistula on the skin implies the presence of distal obstruction, chronic infection, such as tuberculosis, or a foreign body, such as a stone or non-absorbable ligature

LOWER URINARY TRACT INFECTION AND CYSTITIS

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as 'cystitis'. Lower UTIs are much more common in women than in men, particularly in the under 50s. It should be remembered that a lower UTI is often associated with upper tract colonisation and the presence of associated loin pain, pyrexia, rigors and malaise (these symptoms represent complicated infection and should be taken seriously as serious sepsis can ensue).

Isolated infection

A single episode of lower tract infection occurs frequently in females and is rarely complicated.

Recurrent infection

Recurrent infection may be associated with an underlying predisposing cause or may be a result of bacterial resistance. In healthy women, infection after intercourse can occur without any demonstrable abnormality of the urinary tract. Repeated attacks of UTI in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is common and investigation may fail to demonstrate any underlying cause.

Infection in males

Although more common in female adults, the incidence of infection is higher in male infants as underlying urinary tract abnormalities are more frequent. Complicated or recurrent

infection in adult males warrants prompt antibiotic therapy and investigation to exclude an underlying cause.

Infection in pregnancy

The incidence of asymptomatic bacteriuria in pregnant women is twice as high as in non-pregnant women. Simple uncomplicated infection can be treated following urine culture with an appropriate antibiotic that is not contraindicated in pregnancy, such as cephalosporin or ampicillin. Non-responsive infection may require intravenous therapy and an ultrasound scan.

Predisposing causes of urinary tract infection

- Incomplete emptying of the bladder, secondary to bladder outflow obstruction, a bladder diverticulum, neurogenic bladder dysfunction or decompensation of the detrusor muscle.
- A calculus, foreign body or neoplasm.
- Incomplete emptying of the upper tract, dilatation of the ureters associated with pregnancy, or vesicoureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; operation is reserved for those with recurrent infection despite antibiotics or with severe upper tract dilatation.
- Oestrogen deficiency, which may give rise to lowered local resistance.
- Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.
- Diabetes.
- Immunosuppression.

Avenues of infection

Ascending infection from the urethra is the most common route (see Chapter 74). The organisms originate in the bowel, contaminate the vulva and reach the bladder. The passage of urethral instruments may cause infection in either sex, especially when the bladder contains residual urine (Figure 76.39). Other routes are less common and include descending infection from the kidney (tuberculosis), haematogenous spread, lymphogenous spread and spread from adjoining structures (Fallopian tube, vagina or gut).

Bacteriology

Bacterial virulence factors affect the ability of a pathogen to infect the host. The possession of pili (rod-shaped structures) that project from the outer membrane increases adhesiveness. The type of pilus can be used to classify the pathogen involved. *Escherichia coli* is the most common organism followed by *Proteus mirabilis*, *Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or infection with mixed organisms is found in patients with neurogenic bladder dysfunction or those with a longstanding indwelling urethral catheter. These organisms include *Pseudomonas*, *Klebsiella*, *Staphylococcus aureus* and various streptococci. Tuberculous infection is considered below. The presence of pus cells without organisms calls for examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, carcinoma *in situ*, renal papillary necrosis, stones or incomplete treatment of a urinary infection.

Figure 76.39 Complications liable to follow the changing of a urethral catheter in the presence of urethritis (courtesy of CG Scorer, FRCS, London, UK).

Clinical features

These include frequency, pain, haematuria and pyuria. Pyrexia and rigors are not associated with a simple UTI, but are a sign of upper tract infection or septicæmia.

Examination

On examination, there is tenderness over the bladder. Initial and midstream urine specimens should be collected in a male as acute prostatitis may be present (see below), which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment

Treatment should be commenced immediately and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics depend on local likely sensitivities, but would include trimethoprim or one of the quinolones. Failure to respond indicates the need for further investigation to exclude predisposing factors. It is important to check for associated allergies or other drugs or conditions that might preclude the use of some antibiotics (e.g. concomitant administration of methotrexate and trimethoprim (both inhibit tetrahydrofolate reductase)).

Investigation

Investigation may be needed in the male or when recurrent infection occurs. This includes measurement of urinary flow rates and post-void residual urine. IVU, ultrasound scan or CT scanning will usually be carried out together with cystoscopy.

Summary box 76.10

UTI in adults

- Isolated UTI in adults is not infrequent and is more common in women
- Recurrent or complicated infection (haematuria, rigors) warrants appropriate antimicrobial therapy and investigation
- Investigation to exclude a predisposing cause includes urinalysis, microscopy and culture, upper tract imaging and cystoscopy
- *Mycobacterium tuberculosis*, *Neisseria gonorrhoeae* or *Mycoplasma genitalium* should be suspected if pus cells are present but urine culture is negative
- Cancer, especially CIS, masquerading as infection may be diagnosed as abacterial cystitis

Difficult cases may require urodynamic investigation (Summary box 76.10).

SPECIAL FORMS OF LOWER URINARY TRACT INFECTION

Acute abacterial cystitis (acute haemorrhagic cystitis)

The patient presents with severe UTI. Pus is present in the urine but no organism can be cultured. It is commonly sexually acquired, but tuberculous infection and CIS must be ruled out. The underlying causative organism may be *Mycoplasma* or herpes simplex virus. Cyclophosphamide can also cause this problem.

Frequency-dysuria syndrome (urethral syndrome)

This consists of symptoms of lower tract infection but with negative urine cultures. CIS, tuberculosis and interstitial cystitis should be excluded. Most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, adopting general perineal hygiene measures and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

Tuberculous urinary infection

Tuberculous urinary infection is secondary to renal tuberculosis. Early tuberculosis of the bladder commences around the ureteric orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently, tubercles may be seen and, in longstanding cases, there is marked fibrosis and the capacity of the bladder is greatly reduced (Figure 76.40).

Treatment

Tuberculous infection usually responds rapidly to anti-tuberculous drugs but occasionally the involved kidney and ureter have to be removed. If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at risk because of high filling pressures and vesicoureteric reflux. Such

Figure 76.40 Retrograde cystograph showing an exceedingly contracted ('thimble') bladder in a case of tuberculous cystitis.

patients, after appropriate chemotherapy, respond well to bladder augmentation. The ureters may need reimplantation.

Bladder augmentation by ileocystoplasty or caecocystoplasty

The fibrosed supratrigonal bladder is removed and the bladder augmented with a segment of bowel. This may consist of intact caecum, a detubularised segment of ileum or a detubularised ileocaecal segment (see Figures 76.20, 76.21 and 76.22).

Interstitial cystitis (Hunner's ulcer)

For practical purposes, this is confined to women. The first symptom is increased frequency; pain, relieved by micturition and aggravated by jarring and overdistension of the bladder, is another characteristic symptom. In most patients, pyuria and urinary infection are absent. Haematuria also occurs. The aetiology remains as obscure as it was when Guy Hunner described the condition in 1914. It consists of a chronic pancystitis, often with marked infiltration with lymphocytes and macrophages. Fibrosis of the vesical musculature and areas of avascular atrophy of the epithelium occur. Ulceration of the mucosa occurs in the fundus of the bladder. In severe cases, the bladder capacity is reduced to 30–60 mL. The characteristic linear bleeding ulcer is caused by splitting of the mucosa when the bladder is distended under anaesthesia. Inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened. The inflammation may involve the trigone, the urethra and, in severe cases, the peritoneum. Pronounced mast cell infiltration is seen but is not specific. It is important to check urinary cytology and to biopsy the mucosa to exclude underlying neoplastic disease.

On cystoscopy, the characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed. Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Instillation of dimethylsulphoxide results in improvement in some patients. Other drugs that have been tried include intravesical heparin, oral ranitidine and steroid therapy. Patients with severe symptoms may well require cystectomy and orthotopic bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

Alkaline encrusting cystitis

Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of chronic UTI and a plain x-ray shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

Cystitis cystica

Under the influence of chronic inflammation, the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and dysuria.

SCHISTOSOMIASIS OF THE BLADDER

Geographical distribution

The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China's great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide the habitat for the freshwater snail (*Bulinus truncatus*) that is the intermediate host (see Chapter 6).

Mode of infestation

The disease is acquired through exposure of the skin to infected water, which usually occurs while bathing. The free-swimming, bifid-tailed embryos (cercariae) of the trematode *Schistosoma haematobium* penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body but they flourish in the liver where they live on erythrocytes and develop into male and female worms. Sexual maturity having been attained, the nematodes leave the liver and enter the portal vein. The male worm bends into the shape of a gutter (the gynaecophoric canal) into which a female worm nestles, and the pair makes its way towards the inferior mesenteric vein. *Schistosoma haematobium* has an affinity for the vesical venous plexus, which it reaches through the portosystemic anastomotic channels.

Having reached the bladder, the female worm eventually enters a submucous venule which is so small that it completely blocks it. It now proceeds to lay about 20 ova in a chain; each ovum is provided with a terminal spine that penetrates the vessel wall. A heavily infected subject passes hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure causes rupture and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate snail host within 36 hours. Within the snail's liver, the miracidium enlarges and gives rise

to myriads of daughter cysts, which are set free on the death of the snail. A single miracidium begets thousands of cercariae to complete the life cycle.

Clinical features

After penetration of the skin, urticaria lasting about 5 days can occur (swimmer's itch). Following an incubation period of 4–12 weeks, a high evening temperature, sweating and asthma, together with leukocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early sign and symptom of intermittent, painless, terminal haematuria. Men are affected three times more frequently than women.

Examination of the urine

The last few millilitres of an early-morning urine specimen are collected and centrifuged. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts. Antibody detection by enzyme-linked immunoabsorbent assay (ELISA) using *Schistosoma mansoni* adult microsomal antigen (MAMA) can be performed. The test is positive one month after infection and is specific for *Schistosoma mansoni* and *Schistosoma haematobium*.

Cystoscopy

Depending on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following:

- 1 **Bilharzial pseudotubercles** are the earliest specific appearance of the disease (Figure 76.41);
- 2 **Bilharzial nodules** (Figure 72.42) are caused by the fusion of tubercles;
- 3 **'Sandy patches'** are the result of calcified dead ova with degeneration of the overlying epithelium (Figure 76.43);
- 4 **Ulceration** is the result of sloughing of the mucous membrane containing dead ova (Figure 76.44);
- 5 **Fibrosis** is mainly the result of secondary infection;
- 6 **Granulomas**. Bilharzial masses are caused by the aggregation of nodules;
- 7 **Papillomas** are more pedunculated (Figure 76.45);
- 8 **Carcinoma** is a common end result in grossly infected bilharziasis of the bladder that has been neglected for years.

Treatment

Safe and effective drugs are available for the treatment of schistosomiasis, including praziquantel taken in three doses of 20 mg/kg (total 60 mg/kg) 4 hours apart. It takes many months for dead ova to be expelled and, even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system.

Other complications, requiring specific treatment, include the following:

- urinary calculi;
- stricture of the ureters;
- prostatoseminal vesiculitis;

- fibrosis of the bladder and bladder neck (Figure 76.46);
- bilharzial urethral strictures;
- squamous bladder cancer.

NEOPLASMS OF THE BLADDER

In total, 95 per cent of primary bladder tumours originate in transitional epithelium; the remainder arise from connective tissue (angioma, myoma, fibroma and sarcoma) or are extra-adrenal pheochromocytomas.

Figure 76.41 Bilharzial tubercles (courtesy of N Makar).

Figure 76.44 Bilharzial ulcer (courtesy of N Makar).

Figure 76.45 Bilharzial papilloma (courtesy of N Makar).

Secondary tumours of the bladder are common and most frequently arise from the sigmoid and rectum, the prostate, the uterus or the ovaries, although bronchial neoplasms may also spread to the bladder.

Pathology

Benign papillary tumours

The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea anemone (Figures 76.47 and 76.48). Inverted papilloma is a condition in which the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium. It is benign.

CARCINOMA OF THE BLADDER

Histological types of bladder cancer include urothelial, squamous and adenocarcinoma (or mixed, as a result of metaplasia in a transitional cell carcinoma (TCC)). Over 90 per cent are urothelial in origin. Pure squamous carcinoma is uncommon (approximately 5 per cent), except in areas where bilharzia is endemic. Primary adenocarcinoma, which arises either from the urachal remnant or from areas of glandular metaplasia, accounts for 1–2 per cent of cases.

Urothelial cell carcinoma

Aetiology

Cigarette smoking is the main aetiological factor (40 per cent of cancers). Occupational exposure to urothelial carcinogens remains common. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1895 when he recorded a series of tumours in workers in aniline dye factories. Hueper showed that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chlornaphazine;
- 4-chloro-*o*-toluidine;
- *o*-toluidine;
- 4,4'-methylene bis(2-choloroaniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations associated with an increased risk of bladder cancer are:

- textile workers;
- dye workers;
- tyre rubber and cable workers;
- petrol workers;
- leather workers;
- shoe manufacturers and cleaners;
- painters;
- hairdressers;
- lorry drivers;
- drill press operators;
- chemical workers;
- rodent exterminators and sewage workers.

Figure 76.46 Bilharzial contracture of the bladder, with ureteric reflux (courtesy of H Talib, Baghdad, Iraq).

Bladder cancer became a prescribed industrial disease (No. 39) in 1953, and previously exposed workers may be entitled to compensation. Balkan nephropathy is associated with an increased incidence of upper tract urothelial tumours (see Chapter 75).

A series of genetic events has been clearly implicated in cancer formation but is outside the remit of this chapter. Activation of dominantly acting oncogenes such as *ras* and *c-erbB-1* and *-2*, and transcription factors such as E2F3, have been reported in bladder cancer, as has the inactivation of tumour-suppressor genes such as *p53*, *p21*, *p16* and the retinoblastoma gene. Activation of many other genes occurs including those coding for enzymes that dissolve the basement membrane, such as the metalloproteinases (stromelysin, collagenases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors (e.g. vascular endothelial growth factor (VEGF)) and other peptide growth factors such as the epidermal growth factor and its receptor (EGFR) also have a role to play, as well as the fibroblast growth factor and its receptor-3 (FGFR-3) which was found to be altered mostly in non-muscle invasive disease. These changes are common to several tumour types, including prostate cancer (Summary box 76.11). More recently, new approaches through genome-wide association studies allowed the investigation of genetic susceptibility for urothelial cancer. Several new loci were identified, but to date, only two, NAT2 (N-acetyltransferase 2) and GSTM1 (glutathione S-transferase Mu 1) have been demonstrated to be consistent germline susceptibility markers. These genetic markers do not yet have sufficient discriminatory ability to be used for clinical decision making.

Tumour staging and grading

Study of the biological behaviour of transitional cell cancer of the bladder shows that cancers fall into the three following groups. Depth of invasion (T) from the tumour–node–metastasis (TNM) classification and grade (World Health Organization I, II or III) are important factors in planning treatment and determining prognosis in bladder cancer.

- Non-muscle-invasive pTa (Figure 76.48) and pT1 tumours account for 70 per cent of all new cases; the previous terminology of ‘superficial’ bladder cancer in this category has now been abandoned; it is important to distinguish however ‘low-risk’ urothelial cancers which are unlikely to progress, such as well differentiated (G1) pTa tumours (not invading lamina propria), from ‘high-risk’ cancers such as poorly differentiated (G3) pT1 cancers (invading lamina propria), which should be followed up carefully and treated aggressively as necessary. This can be determined by careful histological examination. Single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.
- Muscle-invasive disease (pT2) accounts for 25 per cent of new cases. Such tumours carry a much worse prognosis as they are subject to local invasion and distant metastasis.
- Flat, non-invasive CIS (primary CIS) accounts for 5 per cent of new cases. Unless diagnosed and treated promptly, it carries a poor prognosis (Summary box 76.12). The highest risk non-muscle invasive cancer is found with multifocal poorly differentiated tumours invading lamina propria (pT1G3) in the presence of CIS.

Figure 76.47 Papillary tumour with daughter implantation ('kiss' cancer).

Figure 76.48 Endoscopic photograph of a pTa bladder tumour about to be resected.

Summary box 76.11

Urothelial cell carcinoma of the bladder

- The fourth most common non-dermatological malignancy in men (male–female ratio 3:1)
- Strongly associated with smoking and chemical exposure in western societies
- Strongly associated with *Schistosoma haematobium* infection (bilharzial bladder cancer) in regions where the parasite is endemic
- Reducing in incidence in countries where smoking is decreasing

Summary box 76.12**Bladder cancer staging**

- Cystoscopy and resection of tumour with separate resection of the tumour base is essential for accurate analysis of invasion into detrusor muscle
- Bimanual examination should be performed after resection of the tumour
- Complete urinary tract imaging is required using contrast CT urography, MR or intravenous urography where other techniques are not available. Cross-sectional imaging by CT or MR is essential in high-risk and muscle invasive disease to stage the tumour further including lymph node status for metastasis.

Non-muscle invasive bladder cancer

These are usually papillary tumours that grow in an exophytic fashion into the bladder lumen (Figures 76.47 and 76.48). They may be single or multiple and may appear pedunculated, arising on a stalk with a narrow base, but if the tumours are less well differentiated they are more solid with a wider base. The mucosa around the tumour is often rather oedematous, with angry-looking, dilated blood vessels. These areas may contain *in situ* changes (concomitant CIS).

The urothelium elsewhere in the bladder may appear rather oedematous and velvety; this suggests a generalised 'field change' with the presence of widespread CIS. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TUR), patients with pTa or pT1 disease may develop two problems:

- 1 About 50–70 per cent develop recurrent tumours that may be single or multiple, and the recurrences may occur on one or on many occasions. The recurrent tumours are usually of the same stage or grade as the primary tumour. High-grade, multiple tumours with concomitant CIS are most likely to develop recurrent disease.
- 2 About 15 per cent will develop a recurrent tumour that invades the bladder muscle. The risk of such progression increases with high-grade disease, pT1 disease, multiple primary disease and concomitant CIS. Many urologists now regard the presence of pT1 grade 3 tumours as an indication for offering the patient immediate cystectomy because of the excellent outcome.

This behaviour provides the rationale for performing check cystoscopies. The factors that result in an increased recurrence and progression rate are:

- high grade;
- pT1 disease;
- concomitant CIS;
- multiple primary tumours;
- recurrent disease at the first check cystoscopy three months after diagnosis.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour without concomitant CIS, which does not recur within

the first six months, have an excellent outcome. Patients with recurrent low-grade disease can be treated with intravesical instillations of a chemotherapeutic agent such as mitomycin-C or epirubicin with regular cystoscopic checkups and repeat biopsies, or immunotherapy using regular intravesical instillations of Bacille Calmette–Guérin (BCG), an attenuated form of the anti-tuberculosis vaccine. Patients with high-grade pTa or pT1 disease are at high risk and should be counselled very carefully. The options include immediate cystectomy or a more conservative approach with a course of BCG followed by careful cystoscopic assessment and maintenance instillations. The presence of persistent disease after BCG therapy is reason to offer cystectomy (Summary box 76.13).

Summary box 76.13**Non-muscle-invasive bladder cancer (NMIBC)**

- Does not invade the detrusor muscle but can extend to the lamina propria
- Extension to the lamina propria (pT1) is a significant risk factor for progression to invasive disease, especially if associated with high-grade disease and CIS
- The incidence of recurrence of this disease can be reduced by intravesical chemotherapy and immunotherapy
- High-risk superficial disease (any grade 3 disease) is best managed by BCG immunotherapy followed by radical treatment if disease persists

Muscle-invasive bladder cancer

Muscle-invasive tumours are nearly always solid (Figure 76.49), although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ulcerated, appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood-borne to the lung, liver or bones, is much more common and will cause the death of 30–50 per cent of patients (Summary box 76.14).

Summary box 76.14**Muscle-invasive bladder cancer**

- Muscle-invasive bladder cancer should be staged by an accurate bimanual examination performed under anaesthesia before and after resection of the tumour
- Complete urinary tract assessment should be performed, including CT, MR or IV urography, as well as cross-sectional imaging identify lymph node involvement and distant spread
- Radical primary treatment options include radical cystectomy, urinary diversion and thorough lymph node dissection which tends to be offered as first line, or radical external beam radiotherapy
- Neoadjuvant chemotherapy improves survival rates as well as adjuvant chemotherapy in some cases particularly in the presence of nodal and distant disease
- Locally advanced disease may be downstaged by radiotherapy or chemotherapy to enable salvage cystectomy

In situ carcinoma

The histological appearance of irregularly arranged cells with large nuclei and a high mitotic index replacing the normally well-ordered urothelium is known as CIS. It may occur alone (primary CIS) or in association with a new tumour (concomitant CIS) or it may occur later in a patient who has previously had a tumour (secondary CIS). It can only be diagnosed when a biopsy is examined under the microscope. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis). It carries a risk for the patient of developing a malignant muscle-invasive cancer. Without treatment, 50 per cent will die of invasive bladder cancer. It can be treated initially with intravesical BCG, but failure of response is an indication for cystectomy. CIS cannot be treated with external beam radiotherapy.

Pure squamous cell carcinoma of the bladder

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

Pure adenocarcinoma

Adenocarcinoma accounts for approximately 1–2 per cent of all bladder cancers. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer, and can be treated with partial cystectomy.

CLINICAL FEATURES OF BLADDER CARCINOMA

Painless gross haematuria is the most common symptom and is indicative of a bladder carcinoma until proven otherwise. Often, however, the patient fails to declare the symptom to their GP. The bleeding may give rise to clot formation and clot urinary retention.

Constant pain in the pelvis usually heralds extravesical spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain that is referred to the suprapubic region, groins, perineum, anus and into the thighs.

It is also important to assess the patient as a whole. Many are elderly men who have been lifelong smokers and who suffer from chronic obstructive airway disease or cardiovascular disease. Their suitability for major surgery must be borne in mind.

INVESTIGATION OF BLADDER CARCINOMA

Urine

Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test but a positive result is highly specific, and it is mostly helpful with high grade disease

Figure 76.49 Radical cystectomy specimen showing a large solid bladder cancer with total removal of the bladder and prostate.

and CIS. New tests are being developed based on the presence of antigens such as nuclear matrix proteins (NMP22) or minichromosome maintenance (MCM) proteins, which may be able to detect new or recurrent tumours; and epigenetic events such as methylated panels of markers or microRNA fragments. These tests continue to be under evaluation and are not used routinely.

Blood

Estimation of haemoglobin and the level of serum electrolytes and urea should be carried out.

CT, magnetic resonance, IVU or ultrasound scanning

This should be performed on all patients with painless haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect (Figure 76.50). Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour. Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or if direct invasion of the ureteric wall occurs. Ultrasound scanning should be carried out if the kidney is non-functioning to determine its presence and the possibility of an obstructed system.

Cross-sectional imaging

Non-contrast CT or magnetic resonance (MR) imaging is being used in some centres instead of IVU or ultrasound scanning for the immediate management of patients with gross painless haematuria. For staging when a muscle-invasive bladder cancer is suspected, contrast-enhanced CT is used, ideally before TUR. False-positive pT3 disease can be diagnosed if cross-sectional imaging is carried out soon after TUR. Magnetic resonance imaging is being used more frequently (Figure 76.51) and can demonstrate lymph node metastasis or muscle invasion.

Cystourethroscopy

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be carried out with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra

is inspected at the initial insertion of the instrument (urethros-copy) and the bladder is then examined in a systematic fashion (cystoscopy). Conventional 'white' light cystoscopy has been improved recently by the introduction of photodynamic 'blue' light cystoscopy which relies on the photosensitiser hexaminolevulinate. It is now recommended in patients with high suspicion of the disease and negative initial findings and in follow up of patients with CIS.

Bimanual examination

A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty. Once there is muscle invasion, the differentiation between pT2 and pT3 disease depends on whether a mass is palpable bimanually at the end of the procedure (pT3). When invasion has spread into the prostate in a man or the vagina in a woman, it is classified as pT4a. If the tumour is fixed to the lateral pelvic side wall, it is staged as pT4b.

TREATMENT FOR CARCINOMA OF THE BLADDER

Non-muscle invasive tumours

Endoscopic surgery

The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small pinch biopsies are taken near to and distant from the primary lesion when CIS is suspected (inflamed or velvety appearance). After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale-yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and leave a catheter in the bladder for a few days. In this instance, the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of the endoscopic procedure. Following these procedures, an irrigating catheter is left *in situ* for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin (mitomycin C; 40 mg in 60 mL of fluid) instilled into the bladder before catheter removal decreases the risks of recurrence in patients with pTa and pT1 grade 1 and 2 disease.

Patients with larger solid tumours should have adequate material resected for histological staging and grading. If possible and straightforward, the mass of the tumour should be resected as completely as possible – even when pT2 or pT3 disease is suspected.

Follow up

Most urologists agree that patients with a single low- or medium-grade pTa tumour can safely be treated by resection alone plus a single instillation of mitomycin, followed up with regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumours can be by either resection alone or resection

Figure 76.50 Intravenous urography showing a filling defect in the region of the right ureteric orifice.

followed by a 6-week course of intravesical chemotherapy with mitomycin, doxorubicin or epirubicin.

The treatment of pT1 disease is difficult. Approximately 30 per cent of tumours are understaged at first resection. For this reason, a repeat cystoscopy and resection of the tumour base is advocated within 6 weeks. Some urologists would offer immediate cystectomy to a patient with a high-grade pT1 tumour, particularly if it were multiple or accompanied by CIS, because of the 30–50 per cent risk of progression to muscle invasion. Others will treat such patients by endoscopy followed by immunotherapy with intravesical BCG. The most effective treatment of solitary medium-grade pT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed by reresection of the area after 6 weeks, followed by intravesical BCG.

Follow-up cystoscopies are essential; they may be carried out under local anaesthesia with a flexible cystoscope or under general anaesthesia if the urologist feels that the patient is at high risk of recurrence. They should be performed at three-monthly intervals over the first year; following this the time interval between cystoscopies can be determined according to the presence or absence of further disease. In total, 30 per cent of patients will never develop another tumour so that, if the bladder has remained clear after two years, annual inspection

Figure 76.51 (a) Cross-sectional magnetic resonance imaging showing a 'cystogram' and a bladder cancer. (b) Cross-sectional magnetic resonance imaging showing invasive bladder cancer.

may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk of their disease progressing; although intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle and the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Muscle-invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have five-year survival figures of more than 50 per cent. There is a move towards primary surgical treat-

ment in most centres. The use of systemic chemotherapy with a combination of agents – cisplatin, methotrexate, doxorubicin and vinblastine (M-VAC) or cisplatin plus gemcitabine given before (neoadjuvant) radical cystectomy – has been shown to be of benefit. The current evidence is that neoadjuvant chemotherapy improves survival by about 5–7 per cent.

Radiotherapy

External beam radiotherapy

External beam radiotherapy is usually given at 60 Gy over a 4- to 6-week period. There is a complete response rate of 40–50 per cent. Unfortunately, some patients do not respond and others exhibit only a partial response, with pTa or pT1 tumour remaining in the bladder giving rise to a risk of recurrence. Patients with residual disease after radiotherapy should be offered 'salvage cystectomy' if they are fit. Proponents of radiotherapy claim that it avoids the need to remove the bladder in some patients and allows men to retain potency. Radiotherapy is not without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications can leave the bladder contracted and fibrosed, in which case it may need to be removed for palliative reasons. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Surgery

Partial cystectomy

This should be limited to the treatment of small adenocarcinomas of the bladder.

Radical cystectomy and pelvic lymphadenectomy

This is now standard treatment for localised pT2–pT3 disease without evidence of secondary spread or of CIS that has not responded to BCG. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. Cross-sectional imaging of the pelvis may locally overstage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para-aortic nodes or liver metastases will alter the decision for cystectomy. A bone scan (using technetium-99m (99mTc)) will help to show whether there is spread to bone, and a chest plain x-ray should be performed to exclude pulmonary metastases, although many centres now perform routine CT imaging of the chest preoperatively and it tends to be more sensitive than plain x-ray in detecting small lung lesions.

Operation

Alternative drainage for urine is necessary following removal of the bladder. The standard procedure is to perform an ileal conduit diversion. Male patients should be counselled about the onset of erectile impotence and absent ejaculation following the operation, although in some cases the nerve supply for erectile function can be preserved through careful dissection; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen, avoiding skin creases so that one does not end up with the disaster of a leaking urinary

ileostomy. A decision is made about whether the male urethra is to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary CIS or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy.

The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxicillin, and low-dose heparin or equivalent thrombo-embolic prophylaxis including physical means such as stockings and inflatable devices applied to the legs preoperatively to promote venous circulation.

The abdomen is opened through a midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases, and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. Some surgeons will remove lymph nodes up to the aortic bifurcation or higher with some evidence of improved long-term oncological outcomes. The vessels passing to the bladder from the side wall of the pelvis are ligated and divided; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers's fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligature is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel segment and the ileostomy is created. Meticulous care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually a segment of well vascularised ileum) is created and anastomosed to the urethra after implantation of the ureters.

The operative mortality rate associated with cystectomy used to be considerable but is now <2 per cent. Late complications include urethral recurrence (about 5–8 per cent), which is increased in the presence of multifocal tumours, CIS and, particularly, invasion of prostatic stroma (Figure 76.52).

Leukoplakia

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leukoplakia of the bladder is pre-malignant and results in squamous cancer of the bladder. Careful cystoscopic assessment is required and the condition may require cystectomy.

Endometriosis

Endometriosis within the bladder wall is rare but can have the appearance of a vascular bladder tumour or a tumour that contains chocolate-coloured or bluish cysts. The swelling enlarges

and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing hormone (LHRH) agonists, further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.

INTERNAL AND EXTERNAL URINARY DIVERSION

Indications

Diversion of the urine may be either a temporary expedient to relieve distal obstruction or a permanent procedure when the bladder has been removed or has lost normal neurological control and in cases of incurable fistula or irremovable obstruction.

Methods of urinary diversion

Temporary methods use prosthetic materials, the most common being a urinary catheter. In elderly patients unfit for prostatectomy, and in some patients with terminal carcinoma of the prostate, an indwelling silicone urethral Foley catheter changed every three months is a satisfactory method of drainage. A suprapubic placement is an alternative to urethral placement. The major drawback of long-term catheterisation is infection secondary to the associated bacteriuria that invariably develops. Ureteric obstruction can be relieved by placement of internal 'double-J' pigtail ureteric stents, which can remain for 4–5 months, but are usually changed every three months. As an alternative, a nephrostomy tube, inserted percutaneously by ultrasound and fluoroscopic imaging, is effective when internal stent placement is not feasible.

Permanent urinary diversion

External diversion

Ileal conduit

Permanent urinary tract diversion is most commonly performed by conduit diversion. The ureters are implanted into a short, isolated segment of ileum (Figure 76.53a) or, less commonly, colon. The conduit diverts the urine onwards to a cutaneous stoma for collection in an ileostomy bag. This form of diversion is well established and associated with a low complication rate of less than 10 per cent. The main complication is ureteroileal stricture, which can be limited by spatulation of the distal ureters and an end-to-end anastomosis as described by Wallace (Figure 76.53a). Stenosis at the ileocutaneous site is

Figure 76.52 Urethrectomy specimen from a patient who has previously undergone a radical cystectomy showing new transitional cell tumour formation in the urethra.

less frequent, and a short isoperistaltic conduit limits the formation of a residual urine volume, reducing infection and avoiding the problems of reabsorption of urine. In some cases, when the pelvic area has been subjected to radiation, the lower ureters may be unhealthy; a high division with insertion of the ureters into an ileal loop above the root of the mesentery may then be wiser (Figure 76.54).

The site for the stoma must be chosen before operation, in consultation with a stoma care therapist; the site is marked indelibly on the skin.

Operative details

A coil of ileum, approximately 15–20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The ureters may be joined to the ileum either end-to-side or end-to-end after anastomosing of the distal spatulated ureters to form a plate (Wallace). The distal end of the coil is brought out through an incision made at the site identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2–3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening and the cut edge of the ileum.

Internal urinary diversion

Colon and rectum

The advantage of diverting urine into the colon is that no collecting apparatus is necessary. Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 mL of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces; this can be minimised by constructing an anti-reflux procedure. Various diversions are described; the Mainz II ureterosigmoidostomy creates a cul-de-sac type low-pressure reservoir in the sigmoid into which the ureters are placed (see Figure 76.53b). This reduces reflux, and bowel content, although in contact with urine, takes a direct route to the rectum. In the long term, cancer can develop at long-standing ureterocolic junctions (Figure 76.55).

Bladder reconstruction

Over the past decade, several techniques have been developed to allow a near-spherical urinary reservoir to be formed out of various lengths of bowel that are detubularised. These may consist of ileum, ileum and caecum or sigmoid colon (see Figure 76.53c). The ureters can then be reimplanted in these reservoirs in an anti-reflux manner and the reservoir anastomosed to the membranous urethra in the male (see Figures 76.20, 76.21 and 76.22). This is only indicated when the urethra can be preserved, with no evidence of tumour at the junction between the urethra and the prostate in the male, and bladder neck in the female. About 15–30 per cent of patients cannot empty the neobladder completely and will need to perform intermittent self-catheterisation. The results are good after radical cystectomy, particularly in younger well motivated patients.

Continent urinary diversion

A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the

Figure 76.53 Diversion of urine. Favoured methods: (a) ileal conduit; the ureters are spatulated and anastomosed to ileum end-to-side (insert); (b) ureterosigmoidostomy; (c) ileal neobladder with anti-reflux long afferent limb.

Figure 76.54 Ureteroileostomy (after DM Wallace, FRCS).

ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication-prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or from the appendix, buried in an anti-reflux manner in a submucosal tube (Mitrofanoff; Figure 76.56). Alternatively, a length of ileum can be made into a tube (of a similar size to the appendix) after excision of the antimesenteric ileum and buried in a submucosal tunnel in an antireflux way. Clearly, these operations are complex, with the potential for increased postoperative complications.

Bladder substitution and augmentation

In patients with contraction of the bladder because of tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel, which can then be attached to the trigone or bladder neck after a near-total cystectomy (see Figures 76.20, 76.21 and 76.22). The ureters are then reimplanted. The facility to provide a continence mechanism must be available if needed in the neuro-pathic patient. This may comprise an artificial urinary sphincter or a colposuspension in the female.

Complications of internal diversion

Stricture

Ureterosigmoidostomy was first used by Chaput in 1894. Subsequent modifications included those made by Coffey and Grey Turner. In these methods, the ureters were cut obliquely and pulled into the gut by a stitch – the ends were not stitched to the gut wall – and stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.

Reflux of urine

High-pressure activity within a segment of gut can cause reflux of potentially infected urine at high pressure to the kidneys. In the long term, this can cause renal impairment. The principle of a low-pressure reservoir for both neobladder and ureterosig-

moidostomy (Mainz II) reduces this. In addition, an anti-reflux mechanism, used in neobladder construction, is created by anastomosing the ureters to a non-detubularised 20-cm segment of small bowel, which is in continuity with the neobladder (see Figure 76.53c).

Metabolic consequences of internal diversion

Resorption of solutes

This depends upon the following factors: (1) the area of bowel that is exposed to urine; and (2) the length of time that the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea and progressively diminishing tubular function as a result of pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloraemic acidosis with potassium depletion occur more frequently with ureterosigmoid diversion than with a colonic and ileal neobladder. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In fact, they are seen very infrequently except in patients with pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir. Malabsorption can occur with the loss of terminal ileum and small bowel. The loss of terminal ileum can result in vitamin B12 deficiency and so monitoring of vitamin B12 and folate is recommended after the first year.

Treatment

Patients should be instructed to empty the rectum or conti-

Figure 76.55 An anterior resection of the rectum specimen in a patient aged 18 years who has previously undergone ureterosigmoidostomy for the treatment of bladder exstrophy.

Figure 76.56 A patient with a pT3a bladder cancer who has previously undergone cystoprostatectomy and urethrectomy. A detubularised ileocaecal reservoir has been made with the ureters implanted in submucosal tunnels. The appendix has been implanted within the reservoir in a submucosal tunnel to provide the continence mechanism. The appendix has been brought to the umbilicus and is catheterised 4- to 6-hourly to empty the reservoir.

ment reservoir or neobladder 3-hourly by day. In patients who have undergone ureterosigmoidostomy and in whom acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate three times a day (2 g of each, either as crystals or as tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is administration of intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

Risk of malignancy

There is a risk of cancer developing in bowel used to reconstruct the urinary tract. When the urine is not mixed with faeces,

the incidence is small, becoming significant after 15–18 years. The major risk of malignancy was discovered when ureterosigmoidostomy construction enabled free mixing of urine and faeces. The development of sigmoid reservoirs into which the ureters are inserted has reduced this risk.

LEARNING OBJECTIVES

To understand:

- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for carcinoma of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision-making process for the best treatment option

EMBRYOLOGY

From the primitive urethra, a series of solid epithelial buds develop and become canalised in a matter of weeks. The surrounding mesenchyme forms the muscular and connective tissue of the gland and has a major role in differentiation (stromal epithelium interactions). Skene's tubules, which open on either side of the female urethra, are the homologue of the prostate.

SURGICAL ANATOMY

The contemporary classification of the prostate into different zones was based on the work of McNeal (Figure 77.1). He showed that it is divided into the peripheral zone (PZ), which lies mainly posteriorly and from which most carcinomas arise, and a central zone (CZ), which lies posterior to the urethral lumen and above the ejaculatory ducts as they pass through the prostate; the two zones are rather like an egg in an egg-cup. There is also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. The distal striated urethral sphincter muscle is found at the junction of the prostate and the membranous urethra; it is horseshoe shaped with the bulk lying anteriorly and is quite distinct from the muscle of the pelvic floor (Figure 77.1).

The glands of the peripheral zone (Figure 77.2), lined by columnar epithelium, lie in the fibromuscular stroma, and their ducts, which are long and branched, open into posterolateral grooves on either side of the verumontanum. The glands of the CZ and TZ are shorter and unbranched. All these ducts, the

Figure 77.1 Sagittal diagram of the prostate just lateral to the urethra showing the division into the different zones described by McNeal. The transitional zone is the area from which most benign prostatic hyperplasia (BPH) arises.

common ejaculatory ducts and the prostatic utricle open into the prostatic urethra.

Benign prostate hypertrophy starts in the periurethral transitional zone and, as it increases in size, it compresses the outer PZ of the prostate, which becomes the false capsule. There is also the outer true fibrous anatomical capsule, and external to this lie condensations of endopelvic fascia known as the periprostatic sheath of endopelvic fascia. Between the anatomical capsule and the prostatic sheath lies the abundant prostatic venous plexus. The prostatic sheath is contiguous with the fascia of Denonvilliers, which separates the prostate and its coverings from the rectum. The neurovascular bundles supplying autonomic innervation to the corpora of the penis are in very close

Figure 77.2 A transverse section of the prostate. The peripheral zone is the area from which most prostate cancers arise. The 'adenomatous' zone comprises the central and transitional zones.

relationship to the posterolateral aspect of the prostatic capsule and are at risk of damage during radical cystoprostatectomy or radical prostatectomy; inadvertent diathermy in the region of these nerves may be the cause of uncommon erectile impotence after transurethral prostatectomy.

PHYSIOLOGY

The prostate has a sexual function, but it is unclear how important its secretions are to human fertility. That the normal adult prostate undergoes atrophy after castration was known to John Hunter.

Systemic hormonal influences (endocrine) and local growth factors (paracrine and autocrine)

The growth of the prostate is governed by many local and systemic hormones whose exact functions are not yet known. The main hormone acting on the prostate is testosterone, which is secreted by the Leydig cells of the testes under the control of luteinising hormone (LH), itself secreted from the anterior pituitary under the control of hypothalamic luteinising hormone-releasing hormone (LHRH). LHRH has a short half-life and is released in a pulsatile manner. This pulsatile release is important, as receptors for LHRH will become desensitised if permanently occupied. The administration of LHRH analogues in a continuous, non-pulsatile manner exploits the concept of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5α -reductase, which is found in high concentration in the prostate and the perigenital skin (type II). Other androgens are secreted by the adrenal cortex, but their effects are minimal in the normal male. Oestrogenic steroids are also secreted by the adrenal cortex and, in the ageing male, may play a part in disrupting the delicate balance between DHT and local peptide growth factors, and hence increase the risk of BPH. Increased levels of serum oestrogens, by acting on the hypothalamus, decrease the secretion of LHRH (and hence LH) and thereby decrease serum testosterone levels. Thus, pharmacological levels of oestrogens cause atrophy of the testes and prostate by means of reductions in testosterone.

Other locally acting peptides are secreted by the prostatic epithelium and mesenchymal stromal cells in response to steroid

hormones. These include epidermal growth factor, insulin-like growth factors, basic fibroblast growth factor and transforming growth factors alpha and beta. These undoubtedly play a part in normal and abnormal prostatic growth, but as yet their functions are unclear (Summary box 77.1).

Summary box 77.1

Androgenic hormones

- Androgenic hormones, which drive prostate growth, are derived from several sources
- The majority of testosterone (90 per cent) is secreted by the Leydig cells of the testes under the control of LH, secreted from the anterior pituitary
- Metabolised adrenal androgen accounts for the remaining 5–10 per cent of testosterone
- Testosterone is converted to DHT by the enzyme 5α -reductase type II, which is found in high concentration in the prostate and the perigenital skin
- DHT has five times the potency of testosterone

Elaboration and secretion of prostate-specific antigen and acid phosphatases

Prostate-specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay, and the normal range can differ a little from laboratory to laboratory. There is no real normal upper limit. The levels increase with age, with prostate cancer and with BPH. There are age-related values but, in general, in men aged 50–69 years, a level of about 3–4 ng/mL would prompt a discussion about the need for prostate biopsy. Its level in men with metastatic prostate cancer is usually increased to >30 ng/mL and falls to low levels after successful androgen ablation. Men with locally confined prostate cancer usually have serum PSA levels <10–15 ng/mL. Although PSA is a reliable marker for the progression of advanced disease, it is neither specific nor sensitive in the differential diagnosis of early prostate cancer and BPH, as both diseases are compatible with PSA in the range of 3–15 ng/mL. PSA measurement has superseded measurement of serum acid phosphatase. In summary, about 25 per cent of men with a PSA of 4–10 ng/mL have prostate cancer (i.e. it is not very specific), and about 15–20 per cent of men with a PSA of 1–4 ng/mL have prostate cancer. In general, one would advise men aged 50–69 years to undergo prostate biopsy if the PSA was more than ~3 ng/mL. The threshold would be lower in younger men with a strong family history.

BENIGN PROSTATIC HYPERPLASIA

Aetiology of benign prostatic hyperplasia

Hormones

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of BPH (Summary box 77.2).

Summary box 77.2**Benign prostatic hyperplasia (BPH)**

- Occurs in men over 50 years of age; by the age of 60 years, 50 per cent of men have histological evidence of BPH
- Is a common cause of significant lower urinary tract symptoms in men and is the most common cause of bladder outflow obstruction in men >70 years of age

Pathology

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 53), in which adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands into a false capsule and causes the appearance of the typical 'lateral' lobes.

When BPH affects the subcervical CZ glands, a 'middle' lobe develops that projects up into the bladder within the internal sphincter (Figure 77.3). Sometimes, both lateral lobes also project into the bladder, so that, when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

Effects of benign prostatic hyperplasia

It is important to realise that the relationship between anatomical prostatic enlargement, lower urinary tract symptoms (LUTS) and urodynamic evidence of bladder outflow obstruction (BOO) is complex (Figure 77.4). Pathophysiologically, BOO may be caused in part by increased smooth muscle tone, which is under the control of α -adrenergic agonists (Summary box 77.3).

Figure 77.3 Diagram of late-stage bladder outflow obstruction (BOO) showing enlargement of the prostate from benign prostatic hyperplasia (BPH), trabeculation of the bladder with smooth muscle hypertrophy and fibrosis.

Figure 77.4 Diagrammatic representation of the relation between symptoms of prostatism, benign prostate hyperplasia (BPH) and urodynamic evidence of bladder outflow obstruction (BOO).

Summary box 77.3**Consequences of BPH**

- No symptoms, no BOO
- No symptoms, but urodynamic evidence of BOO
- Lower urinary tract symptoms, no evidence of BOO
- Lower urinary tract symptoms and BOO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

Anatomically, the effects are as follows:

- **Urethra.** The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.
- **Bladder.** If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears trabeculated (Figure 77.5). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

Lower urinary tract symptoms

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term 'prostatism'.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see Chapter 76);
- neuropathic bladder dysfunction as a result of diabetes, strokes, Alzheimer's disease or Parkinson's disease (see Chapter 76);

Figure 77.5 Trabeculation of the bladder from prostatic obstruction. When viewed from within, bands of muscle fibres can be seen – trabeculation. Between these hypertrophied bundles, there are shallow depressions, i.e. sacculations. Sometimes, one of the saccules (rarely two or more) continues to enlarge and forms a diverticulum (courtesy of the late Professor KAL Aschoff, Freiburg, Germany).

- degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
- BOO due to BPH.

LUTS can be described as:

- voiding
 - hesitancy (worsened if the bladder is very full);
 - poor flow (unimproved by straining);
 - intermittent stream – stops and starts;
 - dribbling (including after micturition);
 - sensation of poor bladder emptying;
 - episodes of near retention;
- storage
 - frequency;
 - nocturia;
 - urgency;
 - urge incontinence;
 - nocturnal incontinence (enuresis).

LUTS are usually assessed by means of scoring systems, which give a semi-objective measure of severity. However, some symptoms do not give an accurate picture of the underlying pathophysiological problem. For instance, a man with severe detrusor instability may void only small volumes and hence he will have a sensation of poor flow because low voided volumes (<100 mL) are associated with low flow rates.

Severe irritative symptoms are usually associated with detrusor instability. Post-micturition dribbling is now known not to be a consequence of BOO and is not usually improved by prostatectomy.

Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can

be diagnosed definitively only by pressure-flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10–12 mL/s) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- BPH;
- bladder neck stenosis;
- bladder neck hypertrophy;
- prostate cancer;
- urethral strictures;
- functional obstruction due to neuropathic conditions.

The primary effects of BOO on the bladder are as follows:

- **Urinary flow rates decrease** (for a voided volume >200 mL, a peak flow rate of >15 mL/s is normal (Figure 77.6), one of 10–15 mL/s is equivocal and one <10 mL/s is low (Figure 77.7)).
- **Voiding pressures increase** (pressures >80 cmH₂O are high (Figure 77.8), pressures between 60 and 80 cmH₂O are equivocal and pressures <60 cmH₂O are normal).

The long-term effects of bladder outflow obstruction are as follows:

- The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.
- The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor overactivity (see Chapter 76), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Aside from symptoms, the complications of BOO are as follows:

- Acute retention of urine is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer and confinement to bed on account of intercurrent illness or operation are other causes.
- Chronic retention. In patients in whom the residual volume is >250 mL or so (Figure 77.9), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and

Figure 77.6 Normal flow rate. The voided volume is well in excess of 350 mL, and the maximum flow rate is in excess of 25 mL/s.

Figure 77.7 Diagram of a low flow rate showing a rather low voided volume of about 200 mL, but with markedly decreased flow rate. Such a flow rate could be caused by a urethral stricture, bladder outflow obstruction or a weak detrusor.

Figure 77.8 Conventional urodynamic trace showing detrusor pressure during voiding. There has been a change in scale because the pressure was so high; voiding pressures are increased with a low flow rate. This is diagnostic of bladder outflow obstruction.

filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (Figures 77.10 and 77.11). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.

- Impaired bladder emptying. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.
- Haematuria. This may be a complication of BPH. Other causes must be excluded by carrying out an intravenous urography (IVU), cystoscopy, urine culture and urine cytological examination.
- Other than pain from retention, pain is not a symptom of BOO, and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma *in situ* of the bladder.

Figure 77.10 Intravenous urogram from a patient with symptoms of outflow obstruction and a moderate post-micturition residual urine. The patient did not undergo treatment.

ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS

History

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score which gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflec-

Figure 77.11 Intravenous urogram from the same patient as in Figure 77.10 but carried out some years later. The patient had developed chronic urinary retention and renal impairment owing to upper urinary dilatation.

tion of the degree of 'bother' caused by a patient's symptoms. In addition to the IPSS, a frequency-volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding. These assessments are routinely performed at lower urinary tract clinics but can be elicited by a thorough clinical history (Summary box 77.4).

Summary box 77.4

Investigations of men with LUTS

Essential investigations

- Urine analysis by dipstick for blood, glucose and protein
- Urine culture for infection
- Serum creatinine
- Urinary flow rate and residual volume measurement

Additional investigations

- PSA if indicated
- Pressure-flow studies

Abdominal examination

Abdominal extension is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be exam-

ined to exclude stenosis, and the epididymides are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis, cervical spondylosis, Parkinson's disease and other neurological states may mimic prostatic obstruction. If these are suspected then a pressure-flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer – this is dealt with in the section on prostate cancer. Certainly, men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat, as well as the positive aspects of the early discovery of a small prostate cancer. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If this is in excess of 2.5–4 nmol/L, then transrectal ultrasound scanning (TRUS) plus multiple transrectal biopsies (10 biopsies) should be considered.

If rectal examination is quite normal with no suspicion of cancer, and if no change in treatment policy would in any case result from the diagnosis of early prostate cancer, then there is little point in the routine measurement of PSA in men with uncomplicated BOO. However, because of the fear of future litigation, many find it easier to offer a PSA test.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded, and the voided volume should be in excess of 150–200 mL. This usually means the patient attending a special flow rate clinic. A typical history and a flow rate <10 mL/s (for a voided volume of >200 mL; Figure 77.7) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of post-void residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 mL, and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and symptoms of prostatism may be seen in:

- BOO;
- low voided volumes (characteristically in men with detrusor instability);

- men with weak bladder contractions (low pressure-flow voiding).

Pressure-flow urodynamic studies

Details of these studies are outlined in Chapter 76 (see Figure 77.8). They should be performed on the following patients:

- men with suspected neuropathy (Parkinson's disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (\sim or >15 mL/s);
- men with invalid flow rate measurements (because of low voided volumes).

Blood tests

Serum creatinine, electrolytes and haemoglobin should be measured.

Examination of urine

The urine is examined for glucose and blood; a midstream specimen should be sent for bacteriological examination, and cytological examination may be carried out if carcinoma *in situ* is thought possible.

Upper tract imaging

Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram or ultrasound scan.

Cystourethroscopy

Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethral or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. The decision of whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient's symptoms, signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and the need for surgery.

Transrectal ultrasound scanning

There is no need to carry this out routinely. Accurate estimation of prostatic size is also possible by means of transrectal or transabdominal ultrasound scanning.

MANAGEMENT OF MEN WITH BENIGN PROSTATIC HYPERPLASIA OR BLADDER OUTFLOW OBSTRUCTION

Strong indications for treatment (usually prostatectomy) include:

- **Acute retention** (see Chapter 76) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25 per cent of prostatectomies).
- **Chronic retention and renal impairment:** a residual urine of 200 mL or more, a raised blood urea, hydronephrosis or hydronephrosis demonstrated on urography and uraemic

manifestations (accounts for 15 per cent of prostatectomies).

- **Complications of bladder outflow obstruction:** stone, infection and diverticulum formation.
- **Haemorrhage:** occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed.
- **Elective prostatectomy for severe symptoms:** this accounts for about 60 per cent of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after ten years. Severe symptoms, a low maximum flow rate (<10 mL/s) and an increased residual volume of urine (100–250 mL) are relatively strong indications for operative treatment. The exact cut-off for operative or non-operative treatment will depend on careful discussion between the patient and the urologist (Summary box 77.5).

Summary box 77.5

Options for treatment of LUTS secondary to BPH

- Conservative measures include watchful waiting in conjunction with fluid restriction and reduction in caffeine intake
- Drug therapy is with α -blockers or, in men with a large prostate, a 5 α -reductase inhibitor, or both
- Interventional measures include transurethral resection of the prostate (TURP), which remains the 'gold standard'; consider open prostatectomy for large glands

Acute retention

The management of retention is discussed in detail in Chapter 76. Once the bladder has been drained by means of a catheter, the patient's fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilised by catheterisation. The role of α -adrenergic drugs followed by a trial of catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high.

Special problems in the management of chronic retention

Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of coexistent infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days (see Chapter 76 for general management of retention).

Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as post-obstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient's weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is <9 g/L).

Indications for elective treatment in men with LUTS secondary to BPH

Following careful assessment (see above under Assessment of the patient with lower urinary tract symptoms), the following questions should be answered:

- 1 Have they failed a preliminary trial of medical therapy? Commonly, men will have been treated with α -blockers or 5 α -reductase inhibitors and will have failed treatment. They are then referred by their general practitioner to the urologist.
- 2 Is BOO present? In many cases, the findings of significant symptoms (assessed by symptom scoring), a benign prostate supplemented by the finding of a low maximum flow rate (<10 – 12 mL/s for a good voided volume (>200 mL)) will suffice to make a reasonable working diagnosis of BOO. In some men, particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements, pressure–flow studies will need to be performed.
- 3 How severe are the symptoms and what are the risks of doing nothing? Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>15 mL/s) and good bladder emptying (residual urine <100 mL) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.
- 4 Is the man fit for operative treatment?
- 5 What treatments are available, what are the outcomes and do the side-effects justify treatment?

Treatment

Men with symptoms attending for elective treatment (excluding acute and chronic retention)

Conservative treatment

It is in men with relatively mild symptoms, reasonable flow rates (>10 mL/s) and good bladder emptying (residual urine <100 mL) that careful discussion over the merits and side effects of operative treatment is warranted. Waiting for a period of six months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of anti-muscarinics to help with irritative symptoms is also useful.

Drugs

In men who are very concerned about the development of sexual dysfunction after transurethral resection of the pros-

tate (TURP), the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. α -Adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5 α -reductase inhibitors, which inhibit the conversion of testosterone to DHT, the most active form of androgen. These drugs, when taken for a year, result in a 25 per cent shrinkage of the prostate gland. Both groups of drugs are effective; however, α -blockers work more quickly and, although the 5 α -reductase inhibitors have fewer side effects, they need to be taken for at least six months, and their effect is greatest in patients with large (>50 g) glands. Drug therapy results in improvements in maximum flow rates by about 2 mL/s more than placebo and results in mild (20 per cent) improvement in symptom scores. TURP, however, results in improvements in maximum flow rates from 9 to 18 mL/s and a 75 per cent improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo TURP. They may be best targeted at men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

Operative treatment

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate <12 mL/s. The key is to assess symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

Counselling men undergoing prostatectomy

Men undergoing prostatectomy need to be advised about the following:

- **Retrograde ejaculation.** This occurs in about 65 per cent of men after prostatectomy.
- **Erectile impotence.** This occurs in about 5 per cent of men, usually those whose potency is waning.
- **The success rate.** On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65 per cent of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates (supplemented when necessary by pressure–flow studies) before deciding on treatment.
- **The risk of reoperation.** After TURP, this is about 15 per cent after 8–10 years.
- **The morbidity rate.** Death after TURP is infrequent (<0.5 per cent), severe sepsis is found in about 6 per cent and severe haematuria requiring transfusion of more than two units of blood occurs in about 3 per cent. After discharge, about 15–20 per cent of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.

Figure 77.12 The surgical approaches to the prostate.

Methods of performing prostatectomy

The prostate can be approached (1) transurethrally (TURP), (2) retropubically (RPP), (3) through the bladder (transvesical; TVP) or (4) from the perineum (Figure 77.12).

Transurethral resection of the prostate

TURP has largely replaced other methods unless diverticulectomy or the removal of large stones necessitates open operation; over 95 per cent of men being treated by urologists can be dealt with by TURP. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses, illuminated by a fiberoptic light source, permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves should

receive broad spectrum prophylactic antibiotics with amoxicillin plus cefuroxime or gentamicin intravenously at induction of anaesthesia.

Strips of tissue are cut from the bladder neck down to the level of the verumontanum (Figure 77.13). Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved, and damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection. The 'chips' of prostate are then removed from the bladder using an Ellik evacuator. The risks of hyponatraemia are reduced by using 1.5 per cent isotonic glycine for irrigation, and the recent introduction of continuous-flow resectoscopes makes the procedure swift and safe in experienced hands. At the end of the procedure, careful haemostasis is performed, and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third post-operative day. In men with small prostates or bladder neck dys-synergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a diathermy 'bee-sting' electrode.

Retropubic prostatectomy (Millin)

Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder. With the patient in the Trendelenburg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained, the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and enucleated with a finger. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

Transvesical prostatectomy

The bladder is opened, and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule. In Freyer's operation (1901), the bladder was left open widely and drained by

Figure 77.13 Endoscopic photograph of transurethral prostatectomy.

Terence John Millin, 1903–1980, surgeon, The Westminster Hospital, London, UK, described the operation of retropubic prostatectomy in 1945. Honorary surgeon, All Saints' Hospital for Genitourinary Diseases, London, UK; he was regarded as 'the greatest of Irish urologists' and 'the pioneer of the retropubic space'. To facilitate his operation, he devised a self-retaining retractor that goes by his name and the 'boomerang' needle to close the prostatic capsule. He used to be invited all over the world to operate on VIPs. He was a former President of the Royal College of Surgeons in Ireland. He gave up operating at the age of 57 to enjoy his farm in County Wicklow where he died of laryngeal carcinoma. He played international rugby for Ireland.

Sir Peter Johnston Freyer, 1852–1921, an Irish born surgeon who performed the first successful prostatectomy in 1900 at St Peter's Hospital, London. He used to give a running commentary to his visiting surgeons in French and Hindustani. Surgeon, St Peter's Hospital for Stone, London, UK.

a suprapubic tube with a 16-mm lumen in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle, the bladder wall was closed and the wound drained.

Perineal prostatectomy (Young)

This has now been abandoned for the treatment of BPH.

After treatment

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

Complications

Local

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if clot retention occurs, the patient will need to be readmitted, a catheter will have to be passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one's pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

Sepsis

Bacteraemia is common even in men with sterile urine and occurs in over 50 per cent of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. In men at high risk, the use of prophylactic antibiotics is recommended. Wound infection following open prostatectomy is common if a urethral catheter has been *in situ* for a number of days before the operation. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to frank septicaemia with profound hypotension. A blood culture should be taken and broad spectrum antibiotics with Gram-negative activity given parenterally, e.g. augmentin and gentamicin.

Incontinence

Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any

prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. Damage to the sphincter may occur at open prostatectomy and following transurethral surgery if the resection extends beyond the verumontanum. If pelvic floor physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter. In some patients, detrusor instability contributes to the incontinence. The use of anti-cholinergic agents or imipramine or duloxetine may help.

Retrograde ejaculation and impotence

Impotence in men with good sexual function before surgery is uncommon, but retrograde ejaculation occurs commonly (>50 per cent) because of disruption to the bladder neck mechanism.

Urethral stricture

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulbar urethra. An early stricture can usually be managed by simple bouginage but, later on, it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

Bladder neck contracture

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. Transurethral incision of the scar tissue is necessary.

Reoperation

It is now well known that, after eight years, 15–18 per cent of men with BPH will undergo repeat TURP (the rate after open prostatectomy is about 5 per cent). The reasons include a technically imperfect primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

General complications

Death occurs in about 0.2–0.3 per cent of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be in the order of 1 per cent.

Cardiovascular

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

Water intoxication (also known as TUR syndrome)

The absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for performing the

Fessenden Nott Otis, 1825–1900, a nineteenth century American urologist.

resections and the use of isotonic saline for postoperative irrigation. The treatment consists of fluid restriction.

Osteitis pubis

This is rare.

Newer treatments

In general, newer, minimally invasive treatments occupy a position intermediate between TURP and drug treatment. In the last decade, technological innovations led to the introduction of novel minimally invasive treatments for prostatectomy. Tissue ablative techniques using hyperthermia and laser energy were associated with minimal morbidity and could often be performed as outpatient procedures. Many of the initial studies reporting treatment success were poorly designed and over a short duration. Longer-term follow up and randomised controlled trials have failed to confirm significant benefit from these techniques. More recently, the holmium laser, a pulsed solid-state laser, has been used to enucleate the prostate adenoma. This approach involves excision of parts of the prostate using a cutting laser and then morcellating the excised prostate fragments, which fall back into the bladder so that they can be removed. Morbidity with this procedure is low and short-term results favourable; long-term follow up will be necessary to determine whether this treatment will have a role to play in the management of BOO. The green light laser is now being used to vaporise the prostate tissue, but has not yet been shown to be as durable as holmium laser treatment or TURP, because the amount of tissue removed is usually less. Recently, the development of bipolar resectoscopes, which allow irrigation with normal saline, has allowed the resection of larger prostates without the risk of causing water intoxication.

Intraurethral stents

These devices are possibly helpful in the management of men with retention who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV) (Figure 73.14). These men are rare cases.

BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK

Aetiology

This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular

Figure 77.14 Diagram showing one type of prostatic stent *in situ*.

hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

Clinical syndromes

Owing to muscle hypertrophy or dyssynergia

Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion's disease or 'prostatism sans prostate'). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of BOO.

Owing to fibrosis

The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP.

Treatment

The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

Drugs

The presence of α -adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

α -Blocking drugs

Alfuzosin, 2.5 mg bd to tds (to a total maximum of 10 mg/day), doxazosin, 1 mg nocte (up to a maximum of 8 mg/day), indoramin, 20 mg bd (increased to a total maximum of 100 mg/day in divided doses), prazosin 500 mg bd (maintenance up to 2 mg/day) and terazosin, 1 mg nocte (to a total maximum of 10 mg/day), can be very useful, causing relaxation of the bladder neck. Modified release tamsulosin 400 mg can be taken once daily. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension.

Transurethral incision

Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

Congenital valves of the prostatic urethra

See Chapter 78.

PROSTATIC CALCULI

Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare.

An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. This is considered in Chapter 75.

Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20 per cent organic material.

Clinical features

Prostatic calculi are usually symptomless, being discovered on

Figure 77.15 Endogenous prostatic calculi.

TRUS, on radiography of the pelvis, during prostatectomy or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On radiographs or ultrasound scans, these stones are often seen to form a horseshoe (Figure 77.15) or a circle.

Treatment of prostatic calculi

They usually require no treatment.

Conservative measures

Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection

Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed per urethram at a later date.

Corpora amylacea

Corpora amylacea are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylacea are probably the forerunners of endogenous prostatic calculi.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the most common malignant tumour in men over the age of 65 years. In England and Wales

in 2008, 37 000 men were registered and 10 000 died from it; the corresponding figures in the USA were 186 000 and 28 000, respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15 per cent of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear. Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the PZ of the prostate (Figure 77.2), so 'prostatectomy' for benign enlargement of the gland confers no protection from subsequent carcinoma.

Pathology

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25 per cent of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70 per cent (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

The following types of prostate cancer occur:

- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- impalpable tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);
- early, palpable, localised prostate cancer (T2);
- advanced local prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1), i.e. occult prostate cancer.

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient's lifetime; herein lies the problem with prostate cancer (Summary box 77.6).

Summary box 77.6

Prostate cancer detection

- The incidence has increased, and opportunistic PSA testing has enabled the detection of early-stage disease
- It is not yet clear whether national screening programmes for prostate cancer should be instigated
- Patients should be counselled about the investigations and treatment options available before a PSA test is performed

Screening for prostate cancer

The cancer detection rate using measurement of PSA is between 2 and 4 per cent, and approximately 30 per cent of men with an elevated PSA will have prostate cancer confirmed by biopsy. Unfortunately, 20 per cent of men with clinically significant prostate cancer will have PSA values within the normal range. There is therefore controversy over the usefulness of PSA alone as a screening procedure. One of the two recent prospective screening trials (the other was inconclusive due to contamination) suggests that screening with PSA does prevent death due

to prostate cancer, but that a lot of men must be screened and treated to prevent one death. At present, in Europe, population-based screening is performed only within the confines of clinical trials.

Histological appearances

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be in confluence. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de-differentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 1 and 5. The scores are added to give an overall Gleason score of between 2 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis.

Local spread

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck and trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

Spread by the bloodstream

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

Lymphatic spread

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

Staging using the tumour, node, metastasis (TNM) system (Figure 77.16)

- 1 **T1a, T1b and T1c.** These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5 per cent of the resected specimen; these tumours are usu-

ally well or moderately well differentiated. T1b is a tumour involving >5 per cent of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.

- 2 **T2a** disease presents as a suspicious nodule (Figure 77.17) on rectal examination confined within the prostate capsule and involving one lobe. **T2b** disease involves both lobes.
- 3 **T3** tumour extends through the capsule (T3a, uni- or bilateral extension. T3b, seminal vesical extension).
- 4 **T4** is a tumour that is fixed or invading adjacent structures other than seminal vesicles – rectum or pelvic side wall (Summary box 77.7).

Summary box 77.7

The natural history of prostate cancer

This depends on the stage and grade of disease:

- **T1 and T2**
The progression rate of well-differentiated T1a prostate cancer is very low: 10–14 per cent after eight years. For moderately differentiated tumours, the rate is about 20 per cent
For T1b and T2 tumours, the rate is in excess of 35 per cent
- **T3 and T4 (MO)**
About 50 per cent progress to bony metastases after 3–5 years
- **M1**
The median survival of men with metastatic disease is about three years

Clinical features

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, 'arthritis', anaemia or pancytopenia;
- renal failure;
- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination (Summary box 77.8).

Rectal examination

Rectal examination can detect nodules within the prostate and advanced disease. TRUS may be used to access the local stage and can be combined with a needle core biopsy (Figure 77.18). Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the

Figure 77.16 Tumour, node, metastasis (TNM) staging system for prostate cancer.

Summary box 77.8

The presentation of men with prostate cancer

- Often men are asymptomatic, and detection is by opportunistic PSA testing
- Cancer is detected in men describing LUTS or may present with symptoms from metastatic disease

bladder base and vesicles (Figure 77.19 demonstrates normal vesicles) is diagnostic, as is local extension through the capsule (Figure 77.20).

Prostatic biopsy

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a transrectal biopsy using an automated gun is recommended. Routine local anaesthetic is used to decrease pain. About ten systematic biopsy cores are obtained, as well as biopsy of any suspicious areas. Broad spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis.

If there are associated symptoms of BOO, then either:

- a TURP can be performed, which will provide diagnostic material and symptomatic relief;
- a transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

General blood tests

These are normal in early disease but, in metastatic disease, there may be leuko-erythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products (FDPs).

Figure 77.17 Transrectal ultrasound scan of a T2 nodule in the prostate.

Liver function tests

These will be abnormal if there is extensive metastatic invasion of the liver. The alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gamma-glutamyltransferase.

Prostate-specific antigen

This is discussed earlier in this chapter. It is good at following the course of advanced disease. It is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 nmol/mL is suggestive of cancer and >35 ng/mL is almost diagnostic of advanced prostate cancer. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign.

Acid phosphatase

Acid phosphatase has been superseded by measurement of PSA.

Figure 77.18 Obtaining a specimen of prostatic tissue by means of a TruCut biopsy needle.

Figure 77.19 Transrectal ultrasound scan showing normal seminal vesicles.

Figure 77.20 Transrectal ultrasound scan showing local extension of a T3 prostate cancer.

Radiological examination

X-rays of the chest may reveal metastases in either the lung fields or the ribs. An abdominal x-ray may show the characteristic sclerotic metastases in lumbar vertebrae and pelvic bones (Figure 77.21). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget's disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Cross-sectional imaging with magnetic resonance imaging and TRUS

Magnetic resonance imaging (MRI) with a high tesla magnet (1.5–3 T) is the most accurate method of staging local disease.

Transrectal ultrasound scanning can also be used. Locally

Figure 77.21 Osseous metastases of the pelvic bones in carcinoma of the prostate (courtesy of LN Pyrah, Leeds, UK).

extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (Figure 77.17) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80 per cent of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50 per cent of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

Bone scan

Once the diagnosis has been established, it would be normal to perform a bone scan as part of the staging procedure if the PSA were >10 nmol/mL or if the biopsy showed high-grade cancer. If the PSA is <10 nmol/mL, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (Figure 77.22) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Lymphangiography

This is no longer carried out. If accurate information is required, then pelvic lymphadenectomy can be performed by means of laparoscopic surgery.

Bone marrow aspiration

Sometimes, examination of the bone marrow will reveal the presence of metastatic carcinoma cells.

Treatment of carcinoma of the prostate

Early disease

Curative treatment can only be offered to patients with early disease (T1a, T1b, T1c and T2). T1a disease found incidentally at TURP is by definition low volume and usually well differentiated. This stage can often be managed by active surveillance, with three- to six-monthly digital rectal examination (DRE)

Figure 77.22 Bone scan showing multiple hot-spots suggestive of metastatic disease in a man with prostate cancer.

and PSA measurement, considering treatment if there is evidence of disease progression. The options available for T1b, T1c and T2 disease need to take into account patient age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T3, T4 or any M0) is only palliative (Summary box 77.9).

Summary box 77.9

Treatment and stage

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference
- PSA, DRE and biopsy Gleason grade are used to predict pathological stage
- Localised cancer can be treated by radical prostatectomy, radiation therapy and active monitoring
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy

Radical prostatectomy

Radical prostatectomy is only suitable for localised disease (T1 and T2) and should be carried out only in men with a life expectancy of >10 years. Exclusion of metastases would require a negative bone scan, chest x-ray and a serum PSA <20 nmol/mL. It is a procedure that should be performed only

by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (<2 per cent), which may require the fitting of an artificial urinary sphincter. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Figure 77.23). The bladder neck is reconstituted and anastomosed to the urethra. Recent modifications to this operation by Professor Patrick Walsh of the Johns Hopkins Hospital in Baltimore have led to the realisation that careful dissection in early-stage disease can lead to preservation of the neurovascular bundles that lie behind the prostate. This modification has led to the preservation of erectile function in about 60–70 per cent of cases. Recently, laparoscopic approaches to radical prostatectomy, sometimes supported by robotic techniques, have been introduced.

Radical radiotherapy for early prostate cancer

External beam radiotherapy (EBRT) can be administered in fields that conform to the contours of the prostate, thereby limiting exposure of adjacent tissues. Survival rates following the treatment of T1 and low-volume T2 disease are not greatly different from those following radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30 per cent of treated patients. The treatment of T3 disease which has spread through the capsule of the gland is controversial. Surgery, radiotherapy, androgen ablation or combinations of the above are used. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhoea and, occasionally, late radiation proctitis. Development of erectile dysfunction occurs less frequently than following radical prostatectomy, but is present in up to 30 per cent of cases.

Brachytherapy

Under transrectal ultrasound guidance, radioactive seeds are permanently implanted into the prostate. A computer program converts accurate ultrasound measurements of the prostate gland to construct a plan of the gland. Under anaesthesia, the patient is placed in the lithotomy position and, according to the template plan, seeds are placed through transperineal needles.

Figure 77.23 Radical prostatectomy specimen for a T2a prostate cancer. Preoperative PSA was 6 ng/L; postoperative levels remained undetectable at eight years. The patient is fully continent.

The radioisotopes commonly used are iodine-125 and palladium-103. These isotopes deliver an intense, confined radiation dose, which falls off rapidly to spare the surrounding structures. Brachytherapy is gaining widespread acceptance for the treatment of lower grade low-volume T1 disease. A major factor is the reduced perioperative complications and generally low morbidity. Long-term cancer survival results from institutions specialising in the procedure are encouraging.

Advanced disease

There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with poorly differentiated disease are at risk of a catastrophic event such as spinal cord compression; in these patients, early androgen ablation can prolong the time to complications. Also, patients with local or general symptoms should be offered androgen deprivation.

Orchidectomy

Orchidectomy is performed to carry out androgen ablation in the treatment of locally advanced (T3 or T4) disease or of metastatic disease. In 1941, prostate cancer was shown to be responsive to such treatment by Charles Huggins, the only urologist to win a Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

Medical castration

Medical forms of androgen ablation have been available since the discovery of stilbestrol. The other commonly available treatment to reduce testosterone levels to the castrate range is LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors but, because of their constant presence (rather than the normal diurnal rhythm), they then downregulate them, resulting in cessation of pituitary LH production and, hence, a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase, and it is wise to give flutamide, bicalutamide or cyproterone acetate for this period. LHRH agonists may be given by monthly or three-monthly depot injection.

Other treatments that block the androgen receptor have become available recently. Cyproterone acetate also has some progestogenic effect, while flutamide and bicalutamide are pure anti-androgen. In general, oral anti-androgen monotherapy has not been shown to be as good as LHRH agonists or orchidectomy. New types of drugs affecting the LHRH–androgen axis, such as LHRH antagonists, superpotent androgen receptor antagonists and drugs inhibiting androgen biosynthesis, are in clinical trials. The role of these drugs is yet to be established.

Complete androgen blockade

Complete androgen blockade has been advocated as being likely to result in increased life expectancy and an increased time to progression in a fitter subgroup of men with advanced prostate cancer. The concept is that of abolishing the testicular secretion of testosterone by means of orchidectomy or the use of LHRH

therapy and then inhibiting the effects of adrenal androgenic steroids by means of androgen receptor blockade with flutamide, bicalutamide or the use of cyproterone acetate. Recent overviews of randomised trials do not confirm earlier reports of effectiveness.

General radiotherapy

Radiotherapy for symptomatic metastases is an excellent form of palliative treatment, often producing dramatic pain relief in men with hormone-relapsed prostate cancer that can last up to six months. When multiple sites are involved, intravenous radiopharmaceuticals such as strontium-89 can be employed. Strontium is a bone-seeking isotope that delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease; however, the duration of response has been disappointing.

Chemotherapy

Cytotoxic agents in the treatment of these men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain. Recent trials of docetaxel have shown improvements in survival, but only by a few months.

Summary of treatment

- 1 Incidentally diagnosed T1a and T1b disease.** For men in their 70s, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (<70 years) man with this form of the disease, although even in this group, some men will elect to pursue a conservative course when counselled about risks versus benefits.
- 2 Localised T1c and T2 disease.** In younger, fitter men (<70 years), this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients with low-grade disease. In the elderly patient with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25 per cent, given that progression to metastatic disease is of this order of magnitude after 10 years.
- 3 Locally advanced T3 and T4 disease.** These patients are at significant risk of disease progression. Early androgen ablation is favoured if close follow up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy is standard treatment for younger men with T3 disease.
- 4 Metastatic disease.** Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

PROSTATITIS

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.

Charles Brenton Huggins, 1901–1997, (Canadian born), Professor of Surgery, The University of Chicago, IL, USA, shared the 1966 Nobel Prize for Physiology or Medicine for his discoveries concerning hormonal treatment of prostate cancer.

Acute prostatitis

Aetiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is *Escherichia coli*, but *Staphylococcus aureus*, *Staphylococcus albus*, *Streptococcus faecalis*, *Neisseria gonorrhoeae* or *Chlamydia* may be responsible. The infection may be haematogenous from a distant focus, or it may be secondary to acute urinary infection.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has 'aches' all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defaecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymides and testes may occur. Prolonged treatment with an antibiotic that penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

Treatment

The abscess should be drained without delay:

- The abscess can be drained by perurethral resection – unroofing the whole cavity.
- The perineal route is rarely indicated unless there is marked periprostatic spread.

Chronic prostatitis

Many urologists find the diagnosis of chronic prostatitis and 'prostatodynia' very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

- persistent threads in voided urine;
- prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be the sequel of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as *Chlamydia* species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the post-prostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.

Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.

Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.

Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

Treatment

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim penetrates well into the prostate. If *Trichomonas* or anaerobes are the responsible agent, a rapid response is obtained from administration of flagyl (metronidazole, 200 mg tds for 7 days to both partners). If *Chlamydia* is suspected, doxycycline is the antibiotic treatment of choice. It is uncertain whether prostatic massage helps in eradicating the infection.

Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation. Whether the syndrome has any relationship with the prostate is unclear.

TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30 per cent of cases, there is a history of pulmonary tuberculosis within five years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculous epididymitis, no symptoms being referable to the internal genitalia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuberculous prostatitis usually present with the following:

- urethral discharge;

- painful, sometimes blood-stained, ejaculation;
- mild ache in the perineum;
- infertility;
- dysuria;
- abscess formation.

Special forms of investigation

X-ray sometimes displays areas of calcification in the prostate and/or the seminal vesicles.

Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

Treatment

The general treatment is that for tuberculosis. If a prostatic abscess forms, it should be drained transurethrally.

SEMINAL VESICLES

Acute seminal vesiculitis

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

Chronic seminal vesiculitis

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of

distension and thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

Tuberculous seminal vesiculitis

The clinical features and treatment have been discussed above.

Diverticulum of the seminal vesicle

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent, and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

Cyst of the seminal vesicle

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision similar to that for perineal prostatectomy, if it is large or giving rise to symptoms.

LEARNING OBJECTIVES

To recognise and understand:

- The common congenital abnormalities of the urethra
- The diagnosis and management of urethral trauma
- The diagnosis and management of urethral stricture
- The diagnosis and management of phimosis
- The principles of management of a man with erectile dysfunction
- The common diseases of the penis and the principles of their surgical management

THE MALE URETHRA**Anatomy**

The male urethra is a tubular structure extending from the bladder neck to the external urinary meatus at the tip of the glans penis. It has four components which are named (from proximal to distal), the prostatic, membranous, bulbar and penile urethra. The prostatic urethra extends from the bladder neck to the verumontanum and is compressed on either side by the lateral lobes of the prostate, giving it a slit-like configuration. The verumontanum is a small hillock of tissue indented at its crown by a pit called the utriculus masculinus which marks the proximal extent of the external urethral sphincter and is an important landmark for urologists performing transurethral resection of the prostate. The membranous urethra lies just distal to the verumontanum and is located where the urethra penetrates the pelvic floor and it is the usual site of urethral rupture at the time of a pelvic fracture. It is the primary location of continence as a consequence of the surrounding pelvic floor musculature and external urethral sphincter. The bulbar urethra extends from the membranous urethra to the penoscrotal junction and is anteriorly located within the corpus spongiosum. The penile urethra is normally flattened anteroposteriorly, but distends when filled with fluid. The penile urethra becomes dilated within the glans penis where it is named the 'navicular fossa'.

The external urethral sphincter is composed of circular striated muscle within the urethral wall. The bladder neck contributes to maintenance of continence in the man, although its main role is as a genital sphincter that closes at the time of ejaculation.

Congenital abnormalities**Posterior urethral valves**

Posterior urethral valves occur in around one in 5000–8000 live male births. The valves are membranes which typically lie

just distal to the verumontanum and cause obstruction to the urethra of boys. They are flap valves and so although they are obstructive to antegrade urinary flow, a urethral catheter can be passed retrogradely without any difficulty. The diagnosis is commonly made antenatally with ultrasound which demonstrates bilateral hydronephrosis above a distended bladder. If the diagnosis is not made antenatally, then patients typically present with urinary infection in the neonatal period or with uraemia and renal failure. Rarely the valves are incomplete and the patient is symptom free until adolescence or adulthood when again urinary infection or renal impairment can supervene.

Diagnosis

Posterior urethral valves need to be detected and treated as early as possible to minimise the degree of renal failure. The valves can be difficult to see on urethroscopy because the flow of irrigant sweeps them into the open position. If the bladder is filled with contrast medium, the dilatation of the urethra above the valves can be demonstrated on a voiding cystogram (Figure 78.1). The bladder is hypertrophied and often shows diverticula. Typically, there is vesicoureteric reflux into dilated upper tracts (Summary box 78.1).

Summary box 78.1**Posterior urethral valves**

- Posterior urethral valves are congenital membranes that cause obstruction to the urinary tract in baby boys
- Antenatal ultrasound typically shows urinary tract dilatation
- If not recognised antenatally, they may cause recurrent urinary infection, urinary retention and uraemia
- Treatment is valve destruction accompanied by treatment of urinary infection and renal impairment

Figure 78.1 A voiding cystogram showing a dilated bladder with a dilated prostatic urethra above an obstruction at the level of the posterior urethral valve.

Treatment

Initial treatment is by catheterisation to relieve the back pressure and to allow the effects of renal failure to improve. Definitive treatment is by endoscopic destruction of the valves with continuing supportive treatment of the dilated urinary tract, the recurrent urinary infections and the uraemia (Summary box 78.1).

Hypospadias

Hypospadias occurs in around one in 200–300 male live births and is the most common congenital abnormality of the urethra (see also Chapter 8). There are three characteristic features. Firstly the external meatus opens on the underside of the penis or the perineum, secondly the ventral aspect of the prepuce is poorly developed ('hooded prepuce') and thirdly there is a ventral deformity of the erect penis (chordee).

Figure 78.2 Hypospadias classification.

Hypospadias is classified according to the position of the meatus (Figure 78.2).

- **Glanular hypospadias.** The ectopic meatus is placed on the glans penis, but proximal to the normal site of the external meatus which is marked by a blind pit. Occasionally the two are connected by a channel.
- **Coronal hypospadias.** The meatus is placed at the junction of the underside of the glans and the body of the penis.
- **Penile and penoscrotal hypospadias.** The meatus is on the underside of the penile shaft.
- **Perineal hypospadias.** This is the rarest and most severe abnormality. The scrotum is bifid and the urethra opens between its two halves. There may be testicular maldescent, which may make it difficult to determine the sex of the child.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord, which deforms the penis in a downward direction (chordee).

Treatment

Hypospadias does not cause either obstruction or urinary tract infection. Surgery is indicated to improve sexual function, to correct problems with the urinary stream and for cosmetic reasons. A variety of plastic surgical procedures have been described to correct the chordee and to re-site the urethral opening. Some techniques utilise the foreskin and therefore circumcision should be avoided before the hypospadias has been repaired. Operations for hypospadias are best performed by a paediatric urologist and are typically undertaken before the age of one year (Summary box 78.2).

Summary box 78.2

Hypospadias

- Hypospadias is characterised by the combination of a ventrally placed urethral meatus, a hooded foreskin and chordee
- Avoid circumcision as the prepuce may be used in procedures to correct the abnormality
- Surgical treatment should be undertaken by a paediatric urologist

Epispadias

Epispadias is very rare. In penile epispadias, the urethral opening is on the dorsum of the penis and is associated with an upward curvature of the penis (Figure 78.3). Epispadias often coexists with bladder exstrophy and other severe developmental defects.

Urethral diverticulum

This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon but are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are caused by the longstanding presence of a foreign body such as a stone or calculus in the urethra.

Typically, patients present in adult life with a history of post-micturition dribbling and diagnosis is made at cystoscopy (Figure 78.4) or via a urethrogram. Treatment is often unnecessary, but they can be treated endoscopically by incising the flap of urethral

Figure 78.3 Glandular epispadias.

mucosa between the two lumens, or in severe cases by excision of the diverticulum.

Injuries to the male urethra

Rupture of the bulbar urethra

There is a history of a blow to the perineum, usually due to a fall astride injury. The bulbar urethra is crushed upwards onto the pubic bone, typically with significant bruising. In the days of sailing ships, the common cause was falling astride a spar and the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers and gymnasium accidents astride the beam account for a number of cases. Almost certainly King William I of England died in 1087 following a ruptured bulbar urethra that he sustained when falling off his horse. It is thought that he ruptured the urethra on the saddle's pommel and he subsequently developed urinary retention and sepsis secondary to infection of the haematoma and he died some days after the accident.

Extravasation of urine is common and the extravasated urine is confined in front of the midperineal point by the attachment of Colles' fascia to the triangular ligament and by the attachment of Scarpa's fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall.

Clinical features

The signs of a ruptured bulbar urethra are perineal bruising and haematoma, typically with a butterfly distribution. There is usually bleeding from the urethral meatus and retention of urine is also typically present.

Management

If the diagnosis is suspected, the patient should be treated with appropriate analgesia and antibiotics should be administered. He should be discouraged from passing urine. A full bladder

Figure 78.4 Cystoscopic appearance of a urethral diverticulum. The normal urethra can be seen to extend superiorly to the urethral sphincter, while the blind ending diverticulum is seen inferiorly.

should be drained with a catheter placed by percutaneous suprapubic puncture (Figure 78.5). This reduces urinary extravasation and allows investigations to establish the extent of the urethral injury. If the patient has passed urine when first seen and there is no extravasation, the rupture, if any, is partial and a suprapubic catheter is not usually needed. Diagnosis is made by urethrography using water soluble contrast.

If there is significant extravasation, then the perineal collection should be drained.

If the urethral tear is complete, the suprapubic catheter should remain *in situ* while the bruising and extravasation settle down. A stricture will typically develop at the site of the injury. The optimal treatment is delayed anastomotic urethroplasty after the swelling and bruising have settled down (typically 8–12 weeks later), with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra (Summary box 78.3).

Summary box 78.3

Bulbar urethral injury

- Suspect urethral injury after blunt perineal trauma when the man cannot void, when there is perineal bruising and when there is blood at the urethral meatus
- The safest initial management is to insert a suprapubic catheter
- Beware of urinary extravasation and sepsis in the perineal haematoma
- Delayed urethroplasty is the preferred definitive management of complete disruptions

Rupture of the membranous urethra

Rupture of the membranous urethra typically occurs in association with a fractured pelvis and may be associated with an extra-peritoneal rupture of the bladder. When the pelvis fractures, the membranous urethra is ruptured as it passes through the bony ring of the pelvis. The urethra is elastic at this point, and if the fracture results in only a minor displacement, then the tear may only be partial, but more typically the rupture is complete, such that the two ends are completely displaced, with the develop-

Figure 78.5 (a) Percutaneous puncture of bladder with passage of a guidewire into the bladder followed by dilatation of track over the guidewire (b), thereby allowing placement of catheter into the bladder (c).

ment of a significant interposing haematoma. About 5 per cent of cases of fractured pelvis have an associated urethral injury and such injuries are almost universally seen in men.

Clinical features

The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. Typically there are multiple associated injuries that may be immediately life threatening and the overriding priority is to keep the patient alive by appropriate resuscitation. Under these circumstances, the management of the other injuries takes precedence.

The clinical features include urinary retention, blood at the urethral meatus and a high riding prostate on digital rectal examination. If the diagnosis is suspected, a urethrogram performed with water soluble contrast media is confirmatory (Figure 78.6).

A suprapubic catheter should be inserted as soon as practicable. The distended bladder may be palpable making suprapubic catheterisation straightforward, but often the bruising and swelling associated with the fracture makes this difficult and ultrasound guidance is required. In the presence of a coexistent extraperitoneal bladder injury, no bladder will be apparent on ultrasound examination, and surgical exploration, bladder repair, suprapubic catheter placement and drainage of the retroperitoneal space are needed.

Complications

Urethral disruption injury

The two ends of the urethra, having been torn apart, become separated by a haematoma. With time, this haematoma resolves and is replaced by fibrosis. This pelvic fracture urethral disruption injury is technically not a stricture of the urethra but is often erroneously described as being one. The conventional management of such an injury is delayed surgical reconstruction with excision of the scar tissue and end to end anastomosis. This surgery should be delayed until the patient has recovered from any other injuries and is usually undertaken 3–6 months later. It is a highly challenging technical procedure and should be undertaken only in specialist centres. Some surgeons continue to undertake early attempts to realign the urethral ends endo-

Figure 78.6 An ascending urethrogram demonstrating extravasation of contrast from the membranous urethra at the site of a urethral injury. Note the associated pelvic fracture with disruption of the inferior pubic rami.

scopically, and while there are some successful reports, most experts feel that there is an increased risk of sepsis, (true) stricture, incontinence and erectile dysfunction.

Urinary incontinence

The site of the urethral rupture is at or close to the striated urethral sphincter. If the external urethral sphincter is damaged or destroyed, continence of urine will depend upon the bladder neck mechanism. While this is usually adequate to maintain complete continence (only 5–10 per cent of men suffer stress urinary incontinence after urethroplasty), subsequent surgical manoeuvres, which destroy the bladder neck (such as transurethral prostatectomy), may cause incontinence.

Erectile dysfunction

Erectile dysfunction is common after pelvic fracture with urethral injury and is due to damage of either the cavernosal nerves which innervate the penis or the penile arteries, which also lie close to the site of the urethral disruption. Indeed, surgical treatment of the urethral disruption can itself cause erectile dysfunction by similar mechanisms. If this does occur, treatment is with an orally active agent such as sildenafil, or if that fails with intracavernosal prostaglandin injections, a vacuum device or a penile implant.

Extravasation of urine

This can occur with extraperitoneal rupture of the bladder, pelvic fracture urethral disruption or in the rare cases where the level of the disruption is the prostatic urethra. Urine extravasates in the layers of the pelvic fascia and the retroperitoneal tissues. Treatment is by suprapubic cystostomy. In rare cases where the extravasation persists despite the suprapubic tube, then drainage of the retropubic space and the definitive repair of

the urethral, prostatic or bladder rupture is required (Summary box 78.4).

Summary box 78.4

Pelvic fracture urethral disruption injury

- Suspect the diagnosis in cases of pelvic fracture, when the patient has not voided and when there is blood at the urethral meatus
- A water soluble urethrogram confirms the diagnosis
- Initial management is insertion of a suprapubic catheter
- Surgical exploration is needed if there is coexistent rupture of the bladder
- Delayed anastomotic urethroplasty is the preferred definitive management

Inflammation of the urethra

Inflammatory conditions of the urethra include:

- meatal ulcer
- urethritis
- gonococcal urethritis
- non-specific urethritis
- Reiter's disease
- peri-urethral abscess.

Ulceration of the urethral meatus

Meatal ulcer is an uncommon complication of neonatal circumcision and may develop up to two years after the circumcision. Lack of protection by the prepuce seems to be the primary cause, with friction from clothing and ammoniacal dermatitis also being contributory factors. Devascularisation caused by ligation of the frenular artery may also possibly play a part. The ulcer forms a scab that blocks the meatus and the child can pass urine only by bursting the scab. This hurts, so the boy screams; a tiny amount of blood may be passed as well. The process causes fibrosis, which can result in an acquired pinhole meatus. Local measures to soften the scab and alkalise the urine are often curative although a few do need meatotomy.

Gonorrhoeal urethritis

Gonorrhoea is a sexually transmitted disease caused by *Neisseria gonorrhoeae* (gonococcus), a Gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men. It is transmitted by unprotected sexual intercourse.

Most men have symptoms typical of urethral discomfort and urethral discharge. There is often scalding dysuria. In women it is often asymptomatic. Symptoms, which are present in 50 per cent or less, usually consist of a mild dysuria or slight urethral discharge, which can go unnoticed by the patient. Cervicitis can occur with about 10 per cent suffering from pelvic inflammatory disease (salpingitis), which, if bilateral, may lead to infertility. A mother may transmit gonorrhoea to her newborn during childbirth with the risk that blindness of the child can result. In addition, in both men and women exposed orally or anally, gonococcal infections can cause a predominantly asymptomatic pharyngitis or proctitis.

Investigations

Traditionally the diagnosis was made by identification of pus and gonococci in a Gram-stained urethral smear with subsequent culture. However, more recently PCR-based techniques, which are more sensitive, are the norm.

Complications

Complications are prevented by effective early treatment. In men, complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicaemia and endocarditis are unusual.

Treatment

Treatment is with antibiotics, with ceftriaxone currently the treatment of choice as a consequence of the increasing prevalence of antibiotic resistance to more traditional antibiotics such as ciprofloxacin or penicillin. Contact tracing is important in controlling the spread of the disease and management is usually by a genitourinary physician.

Non-specific urethritis (synonym: non-gonococcal urethritis)

Non-specific urethritis (NSU) is a sexually transmitted infection that in around 40 per cent of cases is due to *Chlamydia trachomatis* with other cases being caused by *Ureaplasma urealytica* or *Mycoplasma genitalium*. The causative agent in up to 50 per cent of cases is unknown.

Clinical features

In men, dysuria and a white mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. The urine appears to be clear but may contain 'threads' or pus cells. Epididymitis is common and urethral stricture can result. In women, the condition is usually asymptomatic although it can present as vaginal discharge or as a form of urethrotrigonitis. It may result in cervicitis or pelvic inflammatory disease.

Treatment

Exclusion of gonorrheal infection is important. Chlamydial infection is diagnosed by PCR techniques on a urethral swab or a urine sample. Treatment with oxytetracycline or doxycycline is usually effective although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. Azithromycin is an alternative treatment taken as a single oral dose. It is important to treat both partners as reinfection is probable if this is not done.

Reiter's disease (synonym: sexually acquired reactive arthritis)

Reiter's disease is an autoimmune disease characterised by the triad of urethritis or diarrhoea, conjunctivitis and polyarthritis. Common triggers include *Chlamydial urethritis*, less commonly gonococcal urethritis and diarrhoea secondary to *Salmonella*,

Figure 78.7 Chronic periurethral abscess.

Shigella or *Campylobacter*. It is an HLA-B27 associated condition. The conjunctivitis (present in around 50 per cent) and arthritis typically occur 1–3 weeks after the primary infection. Diagnosis is made on clinical grounds and treatment is largely symptomatic, although antibiotic treatment of the precipitating infection is important. The urethritis and conjunctivitis frequently subside after a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Periurethral abscess

Periurethral abscesses can be penile, bulbar or chronic.

Penile periurethral abscess

A penile periurethral abscess arises as an acute gonococcal infection of one of the glands of Littre. The tender induration felt on the underside of the penis points and discharges externally, often leaving a fistula. An anterior urethrotomy will encourage the abscess to burst into the urethra. When the abscess lies behind a stricture, it should be opened externally.

Bulbar periurethral abscess

A bulbar periurethral abscess is a spreading cellulitis caused by infection with streptococci and anaerobic organisms, possibly associated with a stricture. Extravasation of urine is not unusual. There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall. Antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by a suprapubic urinary catheter.

Chronic periurethral abscess

A chronic periurethral abscess sometimes results from a long-standing urethral stricture (Figure 78.7). The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.

Hans Conrad Julius Reiter, 1881–1969, President of the Health Service and Honorary Professor of Hygiene, Berlin, Germany, described this condition in 1916. He was subsequently convicted of war crimes as a consequence of his involvement in the death of hundreds of inmates in Buchenwald.

Figure 78.8 Urinary flow rate trace from a patient with a urethral stricture. Note the prolonged flow with the typical plateau shape of the curve.

Urethral stricture

Causes

The common causes of urethral stricture are:

- Inflammatory
 - Secondary to urethritis
 - Secondary to balanitis xerotica obliterans
- Traumatic
 - Bulbar urethral injury
 - Pelvic fracture urethral disruption injury
- Iatrogenic
 - Secondary to urethral instrumentation
 - Secondary to urethral catheterisation
 - Secondary to transurethral prostatectomy
 - Secondary to radical prostatectomy
- Idiopathic.

Pathophysiology

Post-inflammatory strictures are less common since the introduction of effective antibiotic treatment of gonorrhoea. The stricture is most commonly seen in the bulbar urethra but submeatal strictures also occur. There is infection in the periurethral glands which persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within one year of infection but may not cause difficulty in micturition for some time later.

Balanitis xerotica obliterans is a rare condition characterised by fibrosis of the foreskin resulting in phimosis. In around 10 per cent of cases, the glans penis is also affected causing meatal stenosis and, in a proportion of these cases, there is also fibrosis and stricturing of the penile urethra. The cause of the condition is unknown, but the strictures produced are typically long and difficult to treat.

Post-traumatic strictures have been discussed previously.

Post-instrumentation strictures follow endoscopy or catheterisation and may affect any part of the urethra. Some surgeons recommend prophylactic dilatation or urethrotomy before transurethral prostatectomy in order to try to avoid this complication. Some cases of stricture seem to be due to sensitivity to chemicals from a catheter, but most are the result of a combination of trauma, infection and pressure necrosis.

Bladder neck stenosis can occur following transurethral resection of the prostate (TURP) and following radical prostatectomy for the treatment of prostate cancer. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture, although in the man who has undergone radical prostatectomy, this will result in urinary incontinence.

Clinical features

Symptoms are usually hesitancy of micturition, straining to void and a poor urinary stream. The relative youthfulness of the patient often rules out prostatic enlargement, which characteristically occurs after the age of 50. As the stream becomes narrower, micturition is prolonged and is followed by post-micturition dribbling as a result of urine trickling from the dilated urethra proximal to the stricture. Urinary frequency by day and night is common and is due to incomplete bladder emptying, coexistent detrusor overactivity or urinary infection. The urinary flow rate is typically prolonged and plateau shaped (Figure 78.8).

A well-established stricture may be palpable as scarring along the line of the urethra. If the stricture is tight enough, the patient will go into acute retention, although this is rare. If this happens there is a danger that clumsy attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, its lumen will be too narrow to pass even a tiny catheter and suprapubic catheterisation is required.

Urethroscopy allows the stricture to be viewed as a circumferential scar (Figure 78.9). Openings of false passages commemorate previous misguided attempts to pass a urethral catheter.

Urethrography using a water-soluble contrast medium will show the extent and severity of the stricture (Figures 78.10 and 78.11).

Figure 78.9 Urethroscopic appearance of a urethral stricture.

Figure 78.10 Ascending urethrogram showing urethral stricture of the bulbar urethra.

Complications

The most common complication of a urethral stricture is urinary tract infection, which usually responds to antibiotic treatment although there is a tendency for them to recur as a consequence of the increased residual urines within the bladder. Any of the complications of bladder outflow obstruction can occur, including bladder calculi and upper tract dilatation with renal impairment, although the latter is rare. Similarly, retention of urine is also rare, and should be treated by suprapubic catheterisation. Rare complications include urethral diverticulum and para-urethral abscess (Summary box 78.5).

Summary box 78.5

Diagnosis of urethral stricture

- Suspect the diagnosis of urethral stricture in a young man with poor urinary stream
- Diagnosis is made either by visualisation (urethroscopy) or radiologically (by urethrography)
- Urinary infection should be excluded

Treatment

The management of urethral strictures has changed considerably over the past 20 years. The old treatments of urethral dilatation have largely been superseded by endoscopic incision (internal urethrotomy) or by formal reconstruction (urethroplasty). Urethral dilatation still has a place in elderly men with short strictures that recur infrequently and when the stricture is intimately related to the continence mechanism (such as the bladder neck stricture that follows radical prostatectomy). In these patients, occasional dilatation may be preferable to more complex procedures.

Figure 78.11 Gonorrhoeal stricture of the bulbar urethra. Note that some of the contrast has entered the penile veins.

Internal urethrotomy cures around 50 per cent of short strictures. Success rates are highest when the stricture is short and when it is present within the bulbar urethra. In contrast, failure rates are highest in long strictures, strictures within the penile urethra and in recurrent strictures. In patients with recurrent strictures who are unable or unwilling to undergo urethroplasty, then intermittent self-dilatation with soft hydrophilic catheters on a regular (daily) basis can prevent stricture recurrence, although such self-dilatation is needed lifelong.

Short strictures with a clear traumatic history should be treated by urethroplasty since cure rates in excess of 90 per cent can be achieved by excision of the stricture with end to end anastomosis. Therefore, a conventional therapeutic algorithm is to offer an internal urethrotomy to all newly diagnosed strictures (excluding post-traumatic strictures), and to reserve the more major urethroplasty procedures for recurrent strictures.

Urethral dilatation

This is the old treatment for stricture. Under aseptic conditions, the urethra is stretched using graduated dilators. With care and gentleness, the procedure can be performed under local urethral anaesthesia with lignocaine gel. The drawback of dilatation is that it is performed 'blind', so there is always a danger of causing a false passage. This is most likely with an inexperienced operator unfamiliar with the complexities of an individual patient's urethra.

Strictures have been treated by surgeons for centuries and there are many different dilating instruments. A simple stricture may be dilated using metal sounds (Figure 78.12), so called because they were originally used to 'sound' for stones in the bladder. These must be wielded with great care as it is easy to make a false passage.

Endoscopic (internal) urethrotomy

Internal urethrotomy is performed using the optical urethrotome. The stricture is cut under visual control using a knife passed through the sheath of a rigid urethroscope. The stricture is usually cut at the 12 o'clock position, taking care not to cut too deeply into the vascular spaces of the corpus spongiosum that surrounds the urethra. Other cuts can be made

Figure 78.12 Metal dilators ('sounds').

until there is a wide passage through the strictured segment of urethra. Many surgeons leave a catheter for 1–2 days afterwards. A single urethrotomy seems to give a permanent cure of an uncomplicated stricture in about 50 per cent of patients. The main complications are infection and bleeding. It is possible to get lost when trying to cut a way through a very tight stricture and this is especially true when there are false passages because of previous dilatation attempts. Accordingly, a guidewire should be passed through to the bladder prior to incision of the stricture in order to establish the true lumen of the urethra.

Urethroplasty

The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut ends. This operation is possible only if the stricture is relatively short because there must be no tension at the suture line. If an end-to-end anastomosis is not feasible, a large number of different surgical procedures can be used to reconstruct the fibrosed urethra. The operations using myocutaneous flaps of penile and scrotal skin that dominated the field 20 years ago have largely been replaced by operations that utilise free grafts, usually of buccal mucosa, but also occasionally of penile skin, lingual mucosa and bladder mucosa. The advantage of buccal mucosa is that there is a plentiful supply (approximately 6–7 cm can be obtained from each cheek), it is tough with an excellent vascular plexus, it is used to being wet and the donor site cannot be seen. Indeed, the morbidity associated with the donor site is minimal.

Urethroplasty should be considered when the stricture has arisen following trauma, and when a stricture has recurred following endoscopic treatment. The actual technique used should depend upon the site of the stricture, the length of the stricture and the cause of the stricture. Careful preoperative assessment with ascending and descending urethrography is vital.

Anastomotic urethroplasty has a success rate of around 90 per cent while substitution urethroplasty has success rates at ten years of around 80 per cent (Summary box 78.6).

Ahmad Orandi, urological surgeon, Fergus Falls, MN, USA. Born in Iran, he retired in 1991 at the age of 59 and went into the stock market, real estate and pistachio farming in California – a family tradition from Iran, that he restarted as a business called A & R Pistachios, the initials representing his and his wife's names.

Summary box 78.6

Treatment of urethral strictures

- Newly diagnosed strictures are best treated initially by internal urethrotomy with a 50 per cent success rate
- Intermittent self-dilatation increases the success rate of internal urethrotomy alone
- Urethroplasty should be considered in traumatic strictures and in recurrent strictures
- Treatment by intermittent self-dilatation should be considered in strictures closely related to the external sphincter mechanism

OTHER CONDITIONS OF THE URETHRA

Urethral fistula

The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistula arises behind a tight stricture, there may be multiple openings (watering-can perineum). A fistula can also follow urethroplasty if there is necrosis of part of the graft or flap. The stricture should be treated, in which case some fistulae heal themselves. Occasionally, formal urethroplasty is indicated.

Urethral calculi

Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

Clinical features

Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will usually expel it from the urethral meatus. Larger stones get stuck and must be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

A stone formed within the urethra is less likely to cause recognisable symptoms and is usually detected during urethroscopy or bouginage.

Treatment

A stone lodged within the prostatic urethra should be displaced back into the bladder and treated by lithopaxy or suprapubic cystotomy as if it were a bladder stone. Calculi in more distal parts of the urethra are removed by basketing under vision or fragmented *in situ* using the electrohydraulic or ultrasonic lithotripter. It may be necessary to perform a meatotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

Neoplasms

Polyps are a relatively common finding in the prostatic urethra, where they may result from chronic infection. Genital warts acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis. Angioma of the urethra is a very rare cause of urethral bleeding.

Carcinoma of the urethra is relatively rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Though superficial and susceptible to local ablation by diathermy or laser, they are associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen with a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery. Bloody urethral discharge without infection should raise the suspicion that the patient has a urethral tumour.

THE FEMALE URETHRA

Anatomy

The female urethra is around 2–3 cm long, extending from the bladder neck to the external urethral meatus. Continence is maintained by the external striated urethral sphincter, which in women extends for almost the whole length of the urethra. There is extra support from the surrounding pelvic floor musculature. In contrast to men, the female bladder neck has little role in the maintenance of continence.

Abnormalities of the female urethra include:

- prolapse
- stricture
- Fowler's syndrome (dysfunction of the striated urethral sphincter)
- diverticulum
- caruncle
- papillomata acuminata
- carcinoma.

Prolapse (synonym: urethrocele)

Weakening of the tissues that hold the urethra in place can cause it to move and to put pressure on the vagina, leading to the prolapse of the anterior distal wall of the vagina. Urethroceles often occur with cystoceles. Prolapse occurs in later life and is usually, in part, due to the trauma of childbirth. Prolapse of the urethral lining also occurs as a congenital abnormality, when it causes discomfort proportional to the degree of prolapse.

Stricture

Urethral strictures are uncommon in women but may follow urethritis or more commonly the trauma of a difficult labour. Urinary retention is an occasional consequence and is usually chronic. True urethral strictures in women respond well to dilatation.

Fowler's syndrome

This condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the striated urethral sphincter, which can be detected by electromyography. It causes urinary retention in women and should not be confused with a urethral stricture. Urethral dilatation is ineffective and the retention is best treated by intermittent self-catheterisation. There is some evidence that sacral neuromodulation can be effective.

Diverticulum

A urethral diverticulum is more commonly seen in women than in men. Some seem to be congenital while others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Diagnosis is by magnetic resonance imaging (MRI) or by transvaginal ultrasound. Excision of the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter.

Caruncle

This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external meatus. It is composed of highly vascular connective tissue stroma infiltrated with pus cells. There may be frequency of micturition and urethral pain afterwards. Occasionally, there is bleeding. A urethral prolapse is less tender and is not pedunculated. Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

Papillomata acuminata

Papillomata acuminata are the same as the sexually transmitted warts that occur on the penis. They are treated in the same way. In African women, papillomata acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a caesarean section.

Carcinoma of the urethra

This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncles and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones. Treatment by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.

THE PENIS

Anatomy

The penis is composed of three tubular structures. The upper two structures, which are apposed to each other, are called the corpora cavernosa and are anchored posteriorly onto the pubic rami. They provide the erectile function. The third tubular structure is the corpus spongiosum, which contains the urethra and it expands distally to form the glans penis. The corpora cavernosa have an outer covering of tunica albuginea which is relatively inelastic and which also forms the septum between them. The tunica albuginea encloses the erectile tissue itself which has

A **caesarean section** is the operation of delivering the fetus by an incision into the uterus, usually through the abdominal wall. More than one explanation has been given as the origin of the term. The word 'caesarean' could be a derivative of the Latin term 'caedo', which means to cut. The thought that it derives from the name of the Roman Emperor Julius Caesar is untrue as his mother Aurelia successfully gave birth to her son by natural means and later was an advisor to him. The most plausible explanation is that the Roman or Caesarean Law (law during Caesar's time) demanded that when a pregnant woman died, her body could not be buried until the fetus had been removed.)

a trabecular structure with a network of sinusoidal spaces lined by endothelium within which the blood pools during erection. The central arterial blood supply (the central penile artery) is a branch of the internal pudendal artery. Erection occurs when the parasympathetic nerves that innervate the penis cause smooth muscle relaxation with increased arterial inflow and dilatation of the sinusoids, such that blood accumulates within the trabecular spaces.

DISEASES OF THE FORESKIN

Phimosis

Phimosis is overdiagnosed in children (see also Chapter 8). At birth, the foreskin is normally adherent to the glans penis. These physiological adhesions between the foreskin and the glans penis may persist until six years of age or more, giving the false impression that the prepuce will not retract. This condition (sometimes known as physiological phimosis) should not be confused with true phimosis in boys, with scarring of the prepuce such that it will not retract without fissuring of the foreskin (Figure 78.13). In these cases, the aperture in the prepuce may be so tight as to cause urinary obstruction. Urinary difficulty with residual urine and back pressure effects on the ureters and kidney is far more commonly caused by meatal stenosis, which may be masked by the prepuce.

In adults, phimosis is due to scarring of the foreskin as a consequence of balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin), forcible retraction of the foreskin or lichen sclerosus et atrophicus (synonym: balanitis xerotica obliterans or BXO).

BXO is an uncommon condition in which the normally pliant foreskin becomes thickened. It typically becomes whitish in appearance and forms a constricting band (cicatrix) which prevents retraction (Figure 78.14a,b). BXO may also affect the glans penis (causing meatal stenosis) (Figure 78.15) and the penile urethra (causing urethral stricture). As a consequence it is difficult to keep the penis clean, there may be recurrent attacks of balanitis and there is both a problem with hygiene and, in later life, an increased susceptibility to carcinoma.

Treatment.

In a young child with a non-retractile foreskin, no treatment is necessary or appropriate. When the foreskin is mildly scarred, then preputioplasty is possible. For all other cases, circumcision is the appropriate treatment. In cases of BXO, circumcision is often curative, although when the condition affects the glans penis, topical steroid cream may be helpful. In resistant cases, formal meatotomy is necessary. In emergency situations, such as when catheterisation is required, but is impossible, then it is possible to divide the foreskin dorsally under local anaesthetic (a so-called dorsal slit).

Preputioplasty

This is an application of the Heineke Mikulicz principle whereby the tight ring of the foreskin is divided longitudinally and sewn transversely, thereby allowing retraction of the preserved foreskin. There is a recurrence rate and it is only indicated in mild cases with minimal scarring. If it fails, then circumcision is indicated.

Figure 78.13 Non retractile foreskin. Recent history of symptoms. Examination reveals thickening and scarring with a true phimosis (picture courtesy of Kim Hutton).

Circumcision

Apparently, circumcision did not originate among the Jewish people: they took the practice either from the Babylonians or from African tribes, probably the latter. It had been practised in West Africa for over 5000 years.

Indications

In infants and young boys, circumcision is most usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis, BXO (rare under the age of five years), recurrent attacks of balanoposthitis and recurrent urinary tract infections with an abnormal upper urinary tract. Phimosis may result from misguided attempts by parents to expose the glans forcibly.

In adults, circumcision is indicated because of an inability to retract the foreskin for intercourse, for splitting of an abnormally tight frenulum or for recurrent balanitis.

Recently evidence has emerged that circumcision protects against the spread of human immunodeficiency virus (HIV), and a large scale programme of adult circumcision under the auspices of the World Health Organisation is planned for some African countries where HIV is a major health problem.

Technique in an infant

Applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin is to be condemned. To see one boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult.

Figure 78.14 Phimosis secondary to balanitis xerotica obliterans. Note the white and thickened appearance of the preputial skin (a) with a constriction such that the foreskin cannot be retracted (b).

The Plastibell device can be used in infants (Hollister) and its use is shown in Figure 78.16a–c: the ring separates between 5 and 8 days postoperatively.

Technique in adolescents and adults

In adolescents and adults, the following method is preferable. The prepuce is held in artery forceps and put on a gentle stretch. A circumferential incision in the penile skin is made at the level of the corona using a knife. Marking the skin with a pen is often helpful prior to the incision to ensure that excess skin is not removed. The prepuce is then slit dorsally in the midline to within 1 cm of the corona. This converts the foreskin into two flaps connected at the midline anteriorly. When the under-

Figure 78.15 Severe balanitis xerotica obliterans causing meatal stenosis, thickened and scarred preputial and penile skin. There was also a severe penile urethral stricture.

surface of the prepuce has been separated from the glans, the inner layer of each flap is incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the preputial skin. Cutting the remaining connective tissue completes the excision (Figure 78.17a–e). Monopolar diathermy must be avoided in operations on the penis in small boys because there is a danger that the current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision however, and vessels should be secured with bipolar diathermy or with absorbable ligatures. The cut edges of the skin are approximated using interrupted sutures being certain that the frenular vessels are ligated (Summary box 78.7).

Summary box 78.7

Circumcision

- Is most commonly performed for cultural reasons
- Is not indicated for failure of retraction caused by congenital adhesions between the glans penis and the prepuce
- Is indicated when there is true phimosis with balanoposthitis or obstruction to urinary flow
- Never use monopolar diathermy when performing circumcision

Frenulum breve

Phimosis should not be confused with this condition, where the frenulum is short, such that it causes pain when the foreskin is retracted. Another possible presentation is tearing of the frenulum during sexual activity. Treatment is by frenuloplasty, which utilises the Heineke Mikulicz principle to 'lengthen' the frenulum.

Paraphimosis

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell, causing even more pressure within

Figure 78.16 The Plastibel (Hollister) device for circumcision in infants. (a) The foreskin is freed and retracted. (b) After the Plastibel device has been slipped into place over the glans penis, the foreskin is ligated over the groove of the bell and redundant foreskin is cut away. (c) This shows the completed operation (courtesy of Professor Asal Y Izzidien Al-Samarrai, King Saud University, Riyadh, Saudi Arabia).

the obstructing ring of prepuce. Icebags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal

Figure 78.17 (a–e) Stages in circumcision.

slit of the prepuce under local anaesthetic may be enough in an emergency.

Balanoposthitis

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term 'balanoposthitis'. Skin conditions such as lichen planus and psoriasis affect the penis and, indeed, may be localised there. Drug hypersensitivity reactions can affect the skin of the penis. In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Balanoposthitis is associated with penile cancer, diabetes and phimosis. Monilial infections are quite common under the prepuce. Treatment is by broad-spectrum antibiotics and local hygiene measures. If there is associated phimosis, then a circumcision is required.

Preputial calculi

Later in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from the accumulation beneath a non-retractable foreskin of inspissated smegma, urinary salts or both.

INJURIES OF THE PENIS

Avulsion of the skin of the penis

Entanglement of clothing in rotating machinery is the usual cause. Repair is effected by burying the shaft of the penis in the scrotum with subsequent release at the time of a definitive plastic surgical repair.

Fracture of the penis

Fracture of the penis is an uncommon accident, usually occurring when the erect penis is bent violently downwards during intercourse. The forced deformity results in a rupture of the tunica albuginea with immediate extravasation of blood from within the penis. There is typically a loud cracking sound with immediate loss of the erection, and the rapid development of a large bruise around the penis and extending onto the scrotum (Figure 78.18). There may occasionally be an associated urethral injury. Optimal management involves early exploration of the penis with surgical repair of the ruptured tunica albuginea.

Strangulation of the penis

Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.

Other abnormalities of the penis

Erectile dysfunction

Failure to attain or maintain an erection is called erectile dysfunction (ED). It is a symptom, rather than a condition in itself. It can arise as a consequence of psychological issues, but the most common cause is vascular disease, and as such ED is associated with diabetes, hypertension, dyslipidaemia and smoking. Other rarer causes include endocrine disease (hypogonadism and prolactin secreting pituitary tumours), neurological disease (multiple sclerosis, spinal cord injury and prolapsed intervertebral disc), iatrogenic damage to the cavernosal nerves due to radical pelvic surgery (e.g. radical prostatectomy, abdominoperineal excision of the rectum and radical cystectomy), neuropathy secondary to pelvic radiotherapy and drug-induced cases (including anti-hypertensive agents, antidepressants and antipsychotics).

Assessment involves confirmation of the diagnosis by taking a careful history, assessing the patient for underlying risk factors, and trying to identify the rare case that can be cured as opposed to being treated. Physical examination of the genitalia, the blood pressure and assessment of the secondary sexual characteristics is required and biochemical assessment of the blood sugar, the serum lipid profile and the serum testosterone is necessary in all cases.

Treatment for most patients involves the use of the phosphodiesterase type 5 inhibitors (such as sildenafil) with intracavernosal injection of prostaglandin, vacuum pumps and penile implants reserved for resistant cases (Summary box 78.8).

Peyronie's disease

Peyronie's disease is characterised by penile deformity (Figure 78.19), palpable penile plaques within the penis, erectile dys-

Figure 78.18 Penile fracture. Note the extensive bruising of penis and scrotum.

Summary box 78.8

Erectile dysfunction

- The most common cause of erectile dysfunction is atherosclerosis
- Appropriate investigation involves identification of vascular risk factors
- Phosphodiesterase inhibitors are the first line treatment for most men

function and pain on erection. The cause is unknown, but probably involves minor injury to the erect penis with secondary microhaemorrhage beneath the tunica albuginea and secondary fibrosis. The latter results in the palpable plaques that can be identified on examination. The plaques may rarely be calcified (Figure 78.20). The presence of these relatively inelastic plaques causes the erect penis to bend, often dramatically, towards the side of the plaque. The most common direction of deformity is dorsally (towards the abdomen) and the deformity may be so great as to prevent penetrative sexual intercourse.

While the aetiology is uncertain, there is an association with Dupuytren's contracture. The natural history of the condition is that it typically progresses for 18–24 months before stabilising. During this active phase of the disease, surgery is not indicated, and a variety of medical treatments have been tried, although none with any good evidence of benefit.

When the disease has stabilised, the crucial issue is whether the patient is still able to have sexual intercourse. If he can then no treatment is indicated, while if the deformity prevents penetration, or makes it difficult, then corrective surgery is indicated. Using this criterion, only around a quarter of men come to surgery. The most common procedure is the Nesbitt procedure which corrects the deformity by plicating the convex side of the deformity, thereby straightening the penis, with some accompanying loss of length (Summary box 78.9).

Figure 78.19 An artificial erection obtained peri-operatively demonstrating the dorsal deformity of the erect penis that is typical of Peyronie's disease.

Summary box 78.9

Peyronie's disease

- Medical treatments during the active phase have little evidence of efficacy
- The disease has a natural history of 18–24 months active disease before it stabilises
- Surgery may be indicated to correct deformity that interferes with sexual activity
- Surgical treatment will shorten the erect penile length

Chordee

Chordee (French = corded) is a fixed bowing of the penis caused by hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Priapism

Priapism means persistent erection lasting longer than 4 hours and it is a surgical emergency. There are two main types of priapism, ischaemic and non-ischaemic.

Ischaemic priapism

Ischaemic or venogenic priapism is the more common and is due to venous congestion, with consequent thrombosis and ischaemia. The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is most commonly seen as a side effect of medication, most notably anti-psychotic medication and intracavernosal injections, but it can also arise as a complication of a hypercoagulable blood disorder such as sickle cell disease or leukaemia. A tiny proportion of cases are caused by malignant disease in the corpora cavernosa or the pelvis.

Figure 78.20 Penile calcification in Peyronie's disease (courtesy of Dr SS Rawat, Riyadh, Saudi Arabia).

The clinical features are of a painful erection not involving the glans penis. Blood taken from the penis shows hypoxia, hypercapnoea and acidosis, while Doppler scanning shows an absence of blood flow within the penis.

An underlying cause should be excluded. The patient should be referred for specialist urological care. Treatment is an emergency, since a delay of 6–12 hours results in irreversible damage to the corpus cavernosal tissue with subsequent fibrosis and erectile dysfunction. Aspiration of the sludged blood in the corpora cavernosa is the first-line therapy, but if this fails then intracavernosal injection of phenylephrine (an alpha adrenoceptor agonist) is the next line of therapy. If that proves ineffective, it may be necessary to decompress the penis by creating a shunt between the corpus cavernosum and either the glans penis or the corpus spongiosum. The outlook for normal erectile function is poor if treatment is delayed (Summary box 78.10).

Summary box 78.10

Ischaemic priapism

- The characteristic clinical features are a painful erection not involving the glans penis
- Blood gas analysis from the penis shows hypoxia, hypercapnoea and acidosis
- Detumescence should be ideally achieved within 6–12 hours to avoid long-term erectile dysfunction

Non-ischaemic priapism

The rarer form of priapism arises as a consequence of traumatic damage to the central penile artery, usually as a consequence of blunt perineal trauma. A fistula develops between the artery and the sinusoidal space which results in a persistent erection, which in contrast to the ischaemic priapism is painless. Blood gas analysis shows arterial blood and Doppler scanning demonstrates the fistula (Figure 78.21a,b). Treatment is not an emergency, since there is no ischaemia, and is most appropriately achieved by selective arterial embolisation.

CARCINOMA OF THE PENIS

Penile cancer is rare in the UK, with only around 600 cases being recorded annually. It is much more common in other parts of the world, most notably South America, where it is one of the most common cancers.

Aetiology

Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same benefit, with the assumption that smegma is in some way carcinogenic. Human papillomavirus infection with penile warts is a risk factor, as is BXO and smoking. Phimosis and chronic balanoposthitis are known to be contributory factors, and there are definite precarcinomatous states including leukoplakia of the glans, which is similar to the condition seen on the tongue, and carcinoma *in situ* of the penis.

Carcinoma *in situ* of the penis (synonym Bowen's disease, erythroplasia of Queryat)

Carcinoma *in situ* of the penis is typically seen as a red cutaneous patch on the penis. When it occurs on the glans penis, it is known as erythroplasia of Queryat and when it occurs on the shaft of the penis it is called Bowen's disease. There are several

other benign causes of red patches on the penis, and when in doubt a biopsy is indicated. When the diagnosis of carcinoma *in situ* is confirmed, treatment is by means of topical 5-FU cream, CO₂ laser ablation or surgical excision.

Pathology

Carcinoma of the penis is most typically a squamous cell carcinoma arising in the skin of the glans or the prepuce. It may be flat and infiltrating or warty in appearance (Figure 78.22). The former often starts as leukoplakia and the latter results from an existing papilloma. Local growth continues for months or years. T1 tumours are confined to the skin, with T2 tumours invading the corpus spongiosum or the corpus cavernosum. T3 tumours invade the urethra and T4 tumours invade adjacent structures. The earliest lymphatic spread is to the inguinal (N1 and N2 disease) and then to the iliac nodes (N3 disease) (Figure 78.23). Distant metastatic deposits are infrequent.

Clinical features

Many patients present late (Figure 78.24), either because of embarrassment or because of misdiagnosis. About 10 per cent of patients are under 40 years of age. By the time the patient presents, the growth is often large and secondary infection causes a foul bloody discharge. There is typically little or no pain.

Around 50 per cent have inguinal lymph node enlargement at presentation, but the nodal enlargement often reflects infection. In many, the prepuce is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis. Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes can erode the skin (Figure 78.23) of the groin and in rare cases death of the patient can result from erosion of the femoral or external iliac vessels.

Treatment

Management is divided into treatment of the primary tumour and treatment of the inguinal nodes. For the primary tumour surgical excision is the mainstay of treatment, with the tradi-

Figure 78.21 (a) Colour Doppler scan of a high flow (non-ischaemic) priapism showing turbulence at the site of the arterial injury. Compare the high unilateral signal (turbulence) with normal contralateral flow. (b) Selective pudendal arteriogram showing the site of the fistula (the arterial blush) between the central penile artery and the corpus cavernosum.

Figure 78.23 A late presenting squamous cell cancer of the penis.

tional view that a 2 cm margin of normal tissue be removed being superseded by a more recent, more conservative view, such that penile preserving surgery with excision of much lower margins of normal tissue are now accepted. Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with formation of a perineal urethrostomy. Such surgery is indicated even in advanced metastatic disease for reasons of local control.

Treatment of any associated enlarged inguinal lymph nodes should be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment. For palpable nodes, ultrasound-guided fine needle aspiration will confirm the diagnosis and a block dissection of both groins should be undertaken. The management of the nodes when there is no palpable disease is more controversial with most protocols dictating prophylactic lymph node dissection for tumours that are T2 or greater and for those that are poorly differentiated because of the risk of microscopic disease. A recent development is the use of sentinel node biopsy for impalpable nodes in high risk cases.

Management of the pelvic nodes is even more controversial. When they are involved on computed tomography (CT) scanning, surgery probably has little role, but when the iliac nodes are not enlarged in the presence of N2 disease, the options are observation, pelvic lymphadenectomy or radiotherapy. The prognosis for tumours confined to the penis is good with five-year survival rates in excess of 80 per cent. With nodal involvement, the five-year survival rate falls to around 40 per cent (Summary box 78.11).

Buschke–Löwenstein tumour

Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

Figure 78.24 A squamous cell cancer of the penis with an ulcerating groin node.

Summary box 78.11

Carcinoma of the penis

- A relatively uncommon tumour in the UK
- Enlargement of superficial inguinal lymph nodes may be caused by infection or metastatic spread
- Surgery is the mainstay of treatment
- Nodal involvement indicates a poor prognosis

Malignant melanoma of the penis

This is an uncommon tumour, with the principles of management being the same as for squamous cell carcinoma. Blood-borne metastatic disease is, however, more common.

SEXUALLY TRANSMITTED GENITAL INFECTIONS

Genital ulcers

The most common cause of a genital ulcer is genital herpes. Other less common causes include syphilis and chancroid.

Genital herpes

Genital herpes is caused by sexual transmission of the herpes simplex virus (usually type 2, occasionally type 1). Recurrent attacks occur in 50 per cent or more of cases. Pain along the distribution of the sensory nerve, usually the genitofemoral nerve, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow ulcers which are painful. The first attack is typically accompanied by fever and myalgia. In female patients, the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for

up to 14 days if there is radiculitis of the S2 and S3 nerve roots. The diagnosis is made clinically, or when there is doubt by either cell culture or by PCR-based techniques. Acyclovir and valacyclovir have been shown to be effective in treating genital herpes but they do not prevent recurrences.

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

Syphilis

Syphilitic ulcers are typically painless, rubbery and indurated. Due to the spirochaete *Treponema pallidum*, diagnosis was traditionally achieved by dark field microscopy, but modern serological techniques are nowadays more appropriate. The incidence of syphilis is increasing since the advent of the retrovirals used to treat HIV in mid-1990s. Treatment is by use of a long-acting penicillin.

Lymphogranuloma venereum

Lymphogranuloma venereum is a sexually transmitted disease caused by *Chlamydia trachomatis* (Chlamydia A) types L1–L3 and is primarily an infection of the lymphatics and lymph nodes. The primary lesion is a fleeting, painless, genital papule or ulcer which is often unnoticed by the patient. It can affect both sexes. While it was considered rare in developed countries, some recent outbreaks in Europe have occurred, usually in conjunction with HIV.

The inguinal glands become enlarged and painful between two and four months after infection. The masses of nodes mat together above and below the inguinal ligament to give the 'sign of the groove'. The overlying skin reddens and there may be fluctuance. There may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and occasionally the lower limbs. Urethritis and urethral stricture occur in men.

The diagnosis is confirmed clinically and by the detection of antibodies against the organism. Treatment is by a combination of antibiotics, which may include sulphonamides, oxytetracycline and erythromycin. The multilobar lymphatic masses should not be incised; aspiration is permissible to reduce discomfort.

Granuloma inguinale

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is caused by *Klebsiella granulomatis* and is most commonly seen among socially deprived people. The incubation period varies greatly but is typically between 7 and 30 days.

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatous base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may

develop. The ulcerated area may bleed if touched but is usually surprisingly painless. Without treatment, healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short Gram-negative rods within the cytoplasm of the large mononuclear cells. Treatment is by erythromycin, oxytetracycline or streptomycin.

Condylomata acuminata (synonym: genital warts)

Genital warts are caused by infection with human papillomavirus (HPV) and are sexually transmitted. Infection is very common with only a small proportion of infected patients actually having visible warts. Most commonly due to HPV types 6 and 11, these viruses do not cause cervical cancer. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus (Figure 78.25). In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and *Trichomonas* infection and in men syphilis or gonorrhoea. Genital warts may complicate HIV infection.

Treatment is by chemical or physical means. Podophyllin is often effective as a topical application. It is applied to the wart, taking great care to avoid the surrounding skin, and washed off after 6 hours or so. An alternative agent is Imiquimod. If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

Syphilis derives its name from a poem by a physician, Girolamo Fracastoro, published in Venice in 1530. The poem tells of the shepherd Syphilus, who was struck down by the disease as a punishment for neglecting the worship of Apollo. On his return from Haiti to Barcelona in 1493, Columbus 'brought back syphilis, parrots and rare plants'. The King and Queen of Spain received him with the highest honours.

LEARNING OBJECTIVES

To recognise and understand:

- Testicular maldescent and to appreciate the reasons for intervention
- Testicular torsion as a urological emergency
- The management of the common scrotal swellings (varicocele, hydrocele and epididymal cysts)
- The management of testicular tumours
- The treatment options for infertile men

EMBRYOLOGY AND ANATOMY OF THE TESTIS

The testes develop in the retroperitoneum below the kidneys at around the 10th thoracic level. During the 7th week of fetal development, the gubernaculum forms within the folds of the peritoneum. The upper end is attached to the developing testis and the lower end is attached to the fascia between the developing abdominal wall muscles. At the same time an evagination of the peritoneum itself, the processus vaginalis, develops adjacent to the gubernaculum and over the subsequent weeks evaginates through the abdominal wall to create the inguinal canal. The processus vaginalis initially picks up fibres of the internal oblique (which become the cremasteric muscle) and then fibres of the external oblique (which become the external spermatic fascia). As it elongates, the processus carries with it the gubernaculum, which contains muscle fibres, although it is not fully clear what part it plays in testicular descent. What is clear is that the testes lie at the internal inguinal ring at three months' gestation and descend to the scrotum between seven and nine months. This latter descent into the scrotum is accompanied by shortening of the gubernaculum. Final descent from the external ring to the base of the scrotum takes 4–6 weeks and is usually complete by birth.

The mechanisms that result in testicular descent are poorly understood but probably involve Müllerian inhibiting substance. Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

The anatomy of the adult testis reflects its embryonic development. The testicular arteries originate high up in the retroperitoneum from the abdominal aorta, just below the renal arteries. The testicular veins drain into the renal vein on the left and the inferior vena cava on the right. For much of their course, the testicular artery and vein run parallel to the ipsilateral ureter, for which they may be mistaken during retroperitoneal surgery.

The epididymis lies on the posterior aspect of the testis and is palpable as a separate structure, with a head, a body and a

tail. The seminiferous tubules enter the epididymis at the upper end of the epididymis (the head). From the head, sperm travel through the body and tail of the epididymis to enter the vas deferens at the lower pole of the testis. The vas curves up behind the testis and can be felt above the testis as a firm tubular structure entering the external inguinal ring. In the inguinal canal, the vas deferens is invested by the cremasteric muscle along with the other components of the spermatic cord.

INCOMPLETELY DESCENDED TESTIS**Definitions**

Incomplete descent of the testis occurs when the testis is arrested in some part of its normal path to the scrotum. An ectopic testis is a testis that is abnormally placed outside this path (see also Chapter 8).

Incidence

About 4 per cent of boys are born with one or both testes incompletely descended. About two thirds of these reach the scrotum during the first three months of life, but full descent after that is uncommon. The incidence of testicular maldescent at the age of one year is around 1 per cent. The condition is sometimes missed in the neonatal period and only discovered later in life. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In 10 per cent of unilateral cases, there is a family history.

True testicular pain can be situated in the lower abdomen at the level of the internal inguinal ring in accordance with Brown's Law. **Francis Robert Brown**, former Reader in Surgery, St Andrew's University, UK. Brown's law: Pain, produced in an organ which has migrated from its primary position, and which has not acquired an additional nerve supply in its secondary or permanent position, is invariably localised in the primary relative of that organ.

Sir Astley Cooper, 1768–1841, surgeon, Guy's Hospital, London and First President of the Royal College of Surgeons of England, taught that patients with bilateral retained testes were usually sterile, whereupon one of his pupils, a cryptorchid, left the room and committed suicide. At the post-mortem motile spermatozoa were demonstrated.

Pathology

The condition is more common on the right and is bilateral in 20 per cent of cases. In adults, secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal; usually lying extraperitoneally just inside the internal inguinal ring;
- intra-canalicular; it may or may not be palpable (Figure 79.1);
- extra-canalicular; usually at the scrotal neck;
- ectopic; the most common site is within the superficial inguinal pouch which lies just inferior and medial to the superficial inguinal ring. Other rarer ectopic sites include the femoral triangle, the root of the penis and perineum.

Incompletely descended testes are often macroscopically normal in early childhood, but by puberty the testis is typically smaller compared with its intrascrotal counterpart. Microscopic changes are apparent from 1–2 years, including loss of Leydig cells, degeneration of Sertoli cells and decreased spermatogenesis. The higher the testis, the greater the degree of histological change.

Consequences

Infertility

Impaired fertility is a well-recognised consequence of testicular maldescent with paternity rates around two-thirds of normal for unilateral undescended testes and one-third of normal for bilateral undescended testes. Although there has been a recent tendency to undertake surgical orchidopexy earlier in life, evidence to show that this might benefit fertility is currently lacking.

Malignancy

The cancer risk for adults after cryptorchidism in childhood is 5–10 times greater than normal. The most common cancer is a seminoma and, as with fertility, it is unclear whether early orchidopexy reduces the risk of malignancy. However, if a testicular tumour does develop, it is undoubtedly easier to identify in a testis that is within the scrotum.

Figure 79.1 Undescended testes in a boy aged 12 years. Note the bilateral undescended testes with the underdeveloped scrotum. In cases of retractile testis, the scrotum is relatively well developed.

Hernia

Around 90 per cent of boys with an undescended testis have a patent processus vaginalis, although the incidence of a clinically apparent hernia is much lower.

Testicular torsion

The undescended testis is more prone to testicular torsion, largely as a consequence of a developmental abnormality between the testis and its mesentery (Summary box 79.1).

Summary box 79.1

Undescended testis

- Testes that are absent from the scrotum after three months of age are unlikely to descend
- Histological changes in the testis can be seen from one year of age
- An incompletely descended testis tends to atrophy as puberty approaches
- Boys with undescended testes are at greater risk of infertility, testicular malignancy, hernia and testicular torsion

Clinical features

During childhood, the testes are mobile and the cremasteric reflex is active. In some boys, any stimulation of the skin of the scrotum or thigh causes the testis to ascend and to temporarily disappear into the inguinal canal. This is called a retractile testis. In comparison to a true undescended testis, the scrotum of a boy with a retractile testis is normal as opposed to underdeveloped. When the cremaster relaxes, the testis reappears only to vanish when the scrotal skin is touched again. A retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible. It is helpful to have the boy as relaxed as possible and for him to be examined in a warm room, usually in a supine position.

When the testis is impalpable, ultrasound may be helpful in identifying the intracanalicular testis, while laparoscopy may be needed to differentiate between the abdominal testis and a truly absent testis (Summary box 79.2).

Summary box 79.2

Retractile testis

- Retractable testes should be differentiated from true undescended testes
- This is most easily done with the child relaxed in a warm room
- Retractable testes are more common than true undescended testes
- Retractable testes require no treatment

Surgical treatment

Orchidopexy

Orchidopexy is usually performed before the boy reaches 12 months of age in an attempt to prevent the consequences described earlier. The testis and spermatic cord are mobilised

Figure 79.2 The testis is mobilised and retained in a pouch constructed between the dartos muscle and skin.

and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Three manoeuvres help to gain the length required to bring the testis down into the bottom of the scrotum. First the patent processus vaginalis should be identified, separated and ligated. Second the coverings of the spermatic cord (including the cremasteric muscle) should be divided and third, lateral fibrous bands just inside the internal inguinal ring should be divided. Although these techniques are usually effective, the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis which is placed in a pouch constructed between the dartos muscle and the skin (Figure 79.2).

Failure to bring the testis down

Sometimes for a high undescended testis a two-stage surgical procedure is necessary. The testis is mobilised as far as possible and anchored with a suture and the mobilisation is completed six months later. An alternative approach involves initial division of the gonadal artery (which is usually 'tighter' than the vas deferens), such that the testis becomes dependent for its blood supply upon the vasal artery. The second stage procedure involves conventional orchidopexy. Orchidectomy should be considered if the incompletely descended testis is atrophic, particularly in the post-pubertal boy if the other testis is normal.

INJURIES TO THE TESTIS

The testis can be damaged either by blunt or by penetrating trauma. Injuries can range from simple bruising, through significant intra-testicular haematomas to rupture of the tunica albuginea with very significant collections of blood within the tunica vaginalis (haematocele) (Figure 79.3). If the tunica ruptures, the blood can track into the groin and perineum. Ultrasound examination is a useful adjunct to clinical examination and surgical exploration is indicated for significant injuries including testicular rupture. The objective is to repair the tunica albuginea and preserve the testis, but on occasions orchidectomy is necessary (Summary box 79.3).

Summary box 79.3

Scrotal trauma

- Scrotal exploration should be considered when there is massive swelling and pain after scrotal trauma
- Ultrasound is valuable in the assessment of the injury

ABSENT TESTIS

'Vanishing' testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is prenatal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

TORSION OF THE TESTIS

Pathophysiology

Testicular torsion is a condition whereby the testicle twists in such a way that its blood supply becomes compromised. If left untreated, the blood flow to the testicle ceases and the testicle dies. The earlier the surgery to untwist the testis can be undertaken the better the results, with a testicular salvage rate of 100 per cent if the testicle can be untwisted within 6 hours of the torsion taking place compared with an approximate 20 per cent salvage rate if the surgery is delayed for 24 hours.

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. For torsion to occur, one of several abnormalities must be present:

- Inversion of the testis is the most common predisposing cause. The testis is rotated so that it lies transversely or upside down.
- High investment of the tunica vaginalis causes the testis to hang within the tunica like a clapper in a bell (Figure 79.4).
- Separation of the epididymis from the body of the testis permits torsion of the testis on the pedicle that connects the testis with the epididymis (Figure 79.5).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of

Figure 79.3 Longitudinal scan of testicle with haematocele (H) at lower pole.

Figure 79.4 Testicular torsion. (a) Normal attachment. (b) An abnormally high attachment of the tunica vaginalis predisposes to torsion – the ‘bell-clapper’.

Figure 79.5 Testicular torsion. Separation of the testis from the epididymis – torsion about the pedicle between them.

the cremaster favours rotation of the testis around the vertical axis. Straining on stool, lifting of a heavy weight and coitus are all possible precipitating factors. Alternatively, torsion may develop spontaneously during sleep.

Clinical features

Testicular torsion is most common between 10 and 25 years of age, although a few cases occur in infancy. Typically, there is sudden agonising pain in the groin and the lower abdomen. The patient feels nauseated and may vomit. Torsion of a fully descended testis is usually easily recognised. The testis seems high and the tender twisted cord can be palpated above it. The cremasteric reflex is lost.

Differential diagnosis

Redness of the skin and a mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however, in epididymo-orchitis there will usually be dysuria associated with the accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis and makes it worse in torsion.

Torsion of a testicular appendage cannot always be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni). The twisted testicular appendages can sometimes be visible through the scrotal wall. If the diagnosis is made clinically, then conservative management is possible, but if in doubt then surgical exploration should be undertaken with ligation and amputation of the twisted appendage.

Figure 79.6 Idiopathic oedema of the scrotum.

In mumps orchitis the cord is not particularly thickened and the condition is often bilateral.

Idiopathic scrotal oedema is an oddity that occurs between the age of four and 12 years and must be differentiated from torsion. The scrotum is very swollen but there is little pain or tenderness. The swelling is usually bilateral and may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon; occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (Figure 79.6).

Very occasionally, torsion can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus.

Management

The management of the case should be determined primarily on clinical grounds. If there is any doubt as to the diagnosis, then urgent scrotal exploration is indicated. While Doppler ultrasound scanning can confirm the absence of the blood supply to the affected testis, false positive results can be seen, so it is not routinely recommended.

Exploration for torsion should be performed through a scrotal incision. If the testis is viable when the cord is untwisted it should be prevented from twisting again by fixation with non-absorbable sutures between the tunica vaginalis and the tunica albuginea. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement.

In cases where there is a history of pain for several days, the affected testis will be dead. It is not possible to recover such a testis and although little is gained (other than pain relief) by immediate exploration it is necessary to fix the contralateral testis (Summary box 79.4).

VARICOCELE

A varicocele is a varicose dilatation of the veins draining the testis.

Surgical anatomy

The veins draining the testis and the epididymis form the pampiniform plexus. The veins gradually join each other as they traverse the inguinal canal and, at or near the inguinal ring, there are only one or two testicular veins, which pass upwards

Summary box 79.4**Testicular torsion**

- If the diagnosis of testicular torsion is possible, then surgical exploration is indicated
- Prompt exploration, untwisting and fixation is the only way to save the torqued testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed

within the retroperitoneum. The left testicular vein empties into the left renal vein, the right into the inferior vena cava below the right renal vein. The testicular veins usually have valves near their terminations, but these are sometimes absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastrics.

Aetiology

Varicoceles are common, affecting perhaps 15–20 per cent of males. Ninety per cent are left-sided, reflecting the proximal venous anatomy. In some cases, the dilated vessels are cremasteric veins and not part of the pampiniform plexus. The usual cause is absence or incompetence of valves in the proximal testicular vein. While most varicoceles are idiopathic, obstruction of the left testicular vein by a renal tumour or nephrectomy is a cause of varicocele in later life; characteristically, in such cases the varicocele does not decompress in the supine position.

Clinical features

While most varicoceles are asymptomatic, those that are symptomatic tend to present in adolescence or early adulthood when there may be an annoying dragging discomfort that is worse on standing at the end of the day. This presumably reflects distension of the testicular veins. When examined in the erect position, the scrotum on the affected side hangs lower than normal (Figure 79.7), and on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In longstanding cases, the affected testis is smaller and softer than its fellow owing to a minor degree of atrophy.

Ultrasonography can be helpful in the diagnosis of small varicoceles (Figure 79.8) and in older men with an apparently recent onset of varicocele, ultrasonography of the kidneys is important in excluding a left renal tumour.

Varicocele and spermatogenesis

Of all the possible causes of primary infertility, oligozoospermia (reduced numbers of sperm in the ejaculate) is one of the most difficult to treat. Because varicoceles are relatively common, some men with oligozoospermia will have a varicocele, and it is tempting to blame this for the infertility. Certainly the varicocele will tend to 'warm' the testis, which is usually around 2.5°C below rectal temperature, and there is conflicting evidence regarding the effect of this temperature difference upon spermatogenesis. Unfortunately, there is little evidence that

Figure 79.7 Large varicocele in a pendulous scrotum. Note the left inguinal hernia.

Figure 79.8 Ultrasound of a varicocele. Note the dilated veins at the lower pole of the testis.

varicolectomy improves semen quality or the rate of conception.

Treatment

Operation is not indicated for an asymptomatic varicocele. When the discomfort is significant, then embolisation of the gonadal veins is the usual first line intervention. If this is not possible, or if the varicocele recurs (as it does in around 20 per cent after embolisation), then surgical ligation of the testicular veins is the appropriate treatment, although recurrence can occur even after such surgery (Summary box 79.5).

Summary box 79.5**Varicocele**

- Varicocele is a common condition and 90% are left sided
- Development of a left-sided varicocele in later life may indicate the presence of a renal tumour
- They are usually asymptomatic and as such rarely need treatment
- First-line treatment is embolisation in symptomatic cases
- Varicoceles often recur, even after surgical treatment
- The association of varicoceles with subfertility is controversial

HYDROCELE

A hydrocele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica vaginalis. Acquired hydroceles are primary or idiopathic, or secondary to epididymal or testicular disease.

Aetiology

A hydrocele can be produced in four different ways (Figure 79.9):

- 1 By excessive production of fluid within the sac, e.g. a secondary hydrocele
- 2 By defective absorption of fluid; this appears to be the explanation for most primary hydroceles, although the reason why the fluid is not absorbed is obscure
- 3 By interference with lymphatic drainage of scrotal structures
- 4 By connection with the peritoneal cavity via a patent processus vaginalis (congenital).

Hydrocele fluid contains albumin and fibrinogen. If the contents of a hydrocele are allowed to drain into a collecting vessel, the liquid does not clot; however, the fluid coagulates if mixed with even a trace of blood that has been in contact with damaged tissue.

A secondary hydrocele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with some testicular tumours. A secondary hydrocele is usually lax and of moderate size: the underlying testis is palpable. If a tumour is suspected, the hydrocele should not be punctured for fear of needle-track implantation of malignant cells. A secondary hydrocele subsides when the primary lesion resolves.

Clinical features

Hydroceles are typically translucent and it is possible to 'get above the swelling' on examination of the scrotum. The swelling usually surrounds the testis and epididymis such that they may become impossible to palpate separately.

A primary vaginal hydrocele is seen most commonly in middle and later life but can also occur in older children. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the patient presents for treatment. The testis may be palpable within a lax hydrocele, but an ultrasound scan is necessary to visualise the testis if the hydrocele sac is tense. Be wary of an acute hydrocele in a young man since there may be a testicular tumour.

In congenital hydrocele, the processus vaginalis is patent and connects with the peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocele does not always empty it but the hydrocele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocele may be intermittent. Ascites should be considered if the swellings are bilateral.

Encysted hydrocele of the cord is a smooth oval swelling near the spermatic cord, which is liable to be mistaken for an inguinal

Figure 79.9 (a) Vaginal hydrocele (very common); (b) 'infantile' hydrocele; (c) congenital hydrocele; (d) hydrocele of the cord.

Figure 79.10 Lord's operation. A series of interrupted absorbable sutures is used to plicate the redundant tunica vaginalis. When these are tied, the tunica bunches at its attachment to the testis.

hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

Treatment

Congenital hydroceles are treated by herniotomy if they do not resolve spontaneously (see Chapter 8).

Small acquired hydroceles do not need treatment. If they are sizeable and bothersome for the patient, then surgical treatment is indicated. Established acquired hydroceles often have thick walls. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. Lord's operation is suitable when the sac is reasonably thin-walled (Figure 79.10). There is minimal dissection and the risk of haematoma is reduced. Eversion of the sac with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum is an alternative (Jaboulay's procedure) (Figure 79.11).

Aspiration of the hydrocele fluid is simple, but the fluid always reaccumulates within a week or so. It may be suitable for men who are unfit for scrotal surgery, although hydrocele surgery can be undertaken under local anaesthetic. Aspiration can result in bleeding into the hydrocele sac and haematocele formation. Injection of sclerosants such as tetracycline is effective but painful (Summary box 79.6).

Filarial hydroceles and chyloceles

Filarial hydroceles and chyloceles account for up to 80 per cent of hydroceles in tropical countries where the parasite *Wucheria bancrofti* is endemic. Filarial hydroceles follow repeated attacks

Edward Gibbon, 1737–1794, the author of 'The Decline and Fall of the Roman Empire', was greatly embarrassed by a large hydrocele. The second time that it was tapped it became infected, and Gibbon died a few days later. The hydrocele was associated with a large scrotal hernia which had probably been punctured.

Anton Nuck, 1650–1692, Professor of Anatomy and Medicine, Leiden, The Netherlands.

Peter Herent Lord, contemporary, formerly surgeon, Wycombe General Hospital, High Wycombe, UK, described his operation for hydrocele in 1964 and his procedure for haemorrhoids in 1968.

Figure 79.11 Jaboulay's procedure. The hydrocele sac is everted and anchored with sutures.

Summary box 79.6

Hydrocele

- A hydrocele is a collection of fluid within the tunica vaginalis
- Primary hydroceles surround the testis and transilluminate brightly
- Ultrasound examination is valuable when the testis and epididymis are impalpable
- Hydroceles can be treated conservatively unless they are large and symptomatic
- Surgery is the mainstay of treatment
- Testicular malignancy is an uncommon cause of hydrocele that can be excluded by ultrasound examination

of filarial epididymo-orchitis. They vary in size and may develop slowly or very rapidly. Occasionally, the fluid contains liquid fat, which is rich in cholesterol. This is caused by rupture of a lymphatic varix with discharge of chyle into the hydrocele. In longstanding chyloceles, there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases. Treatment is by rest and aspiration. The more usual chronic cases are treated by excision of the sac.

Haematocele

The most common cause of a haematocele is vessel damage during needle drainage of a hydrocele. Prompt refilling of the sac associated with pain, tenderness and reduced transillumination will confirm the diagnosis. Acute haemorrhage into the tunica vaginalis sometimes results from testicular trauma with or without testicular rupture. If the haematocele is not drained, the blood within it clots (Figure 79.12). It becomes painless and may be mistaken for a testicular tumour. Indeed, a tumour may present as a haematocele. Ultrasound scanning usually helps with the differential diagnosis.

CYSTS ASSOCIATED WITH THE EPIDIDYMIS

There are several types of cyst associated with the epididymis including epididymal cysts and spermatoceles.

Figure 79.12 A longstanding haematocele. The testis has been flattened by prolonged pressure.

Epididymal cysts

These are filled with a crystal-clear fluid. They are very common, usually multiple and vary in size at presentation. They represent cystic degeneration of the epididymis. Cysts of the epididymis are usually found in middle age and are often bilateral. The clusters of tense cysts feel like tiny bunches of grapes that lie posterior to and quite separate from the testis. They should transilluminate brilliantly. The diagnosis can be confirmed by ultrasound (Figure 79.13).

Aspiration is useless because the cysts are usually multilocular. If they are causing discomfort, they should be excised. While single large cysts can be excised separately, recurrent or multilocular cysts usually require partial or total epididymectomy. Excision should be expected to interfere with the transportation of sperm from the testis on that side and young men should be counselled regarding this.

Cysts of a testicular appendage

Cysts of a testicular appendage are usually unilateral and are felt as small globular upper pole swellings. Such cysts are liable to torsion and should be removed if they cause symptoms. They are usually very small.

Spermatocele

This is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis. A spermatocele typically lies in the epididymal head above and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatoceles are usually small and unobtrusive. Small spermatoceles can be ignored. Larger ones should be aspirated or excised through a scrotal incision (Summary box 79.7).

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

A patient with a **spermatocele** often complains that he has a 'third testicle'. He feels lucky that he is unduly provided! The story goes that, in the 14th century, on petition from a patient with a spermatocele, the Pope granted a gentleman to marry two wives because he had 'three testicles'.

Summary box 79.7**Cysts associated with the epididymis**

- Lie posterior to and separate from the testis and they transilluminate
- Diagnosis can be confirmed by ultrasound examination
- Can be treated conservatively unless large or uncomfortable

EPIDIDYMO-ORCHITIS

Inflammation confined to the epididymis is epididymitis; infection spreading to the testis is epididymo-orchitis.

Pathophysiology

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. A general rule is that epididymitis arises in sexually active young men from a genital infection, while in older men it more usually arises from a urinary infection or may be secondary to an indwelling urethral catheter.

In young sexually active men, the most common cause of epididymitis is now *Chlamydia trachomatis*, but gonococcal epididymitis is still occasionally seen. In older men with bladder outflow obstruction, epididymitis may result from a urinary infection – it is proposed that a high pressure in the prostatic urethra might cause reflux of infected urine up the vasa. Blood-borne infections of the epididymis are less common but may be suspected when there is *Escherichia coli*, streptococcal, staphylococcal or *Proteus* infection without evidence of urinary infection and are presumably the only possible mechanism in men who have previously undergone a vasectomy. Acute epididymo-orchitis can follow any form of urethral instrumentation. It is particularly common when an indwelling catheter is associated with infection of the prostate

Clinical features

While there may be initial symptoms of a urinary or a genital infection, such symptoms are not always seen. The development of an ache in the groin and a fever can herald the onset of epididymitis. The epididymis and testis swell and become

painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis. Urinalysis will usually show leukocytes and may show a formal urinary tract infection. Ultrasound is useful in the initial assessment of epididymitis and will identify abscess formation. In young men, urethral swabs should be taken for chlamydial testing.

In adolescents the differential diagnosis is testicular torsion and if there is any clinical doubt as to the diagnosis then testicular exploration should be performed.

Resolution may take 6–8 weeks to complete. Occasionally, an abscess can form that needs surgical drainage. Other complications include testicular atrophy, development of a chronic epididymitis and infertility.

Treatment

Either doxycycline (100–200 mg daily) or a quinolone should be the initial treatment in young men. There should be contact tracing of the partner and treatment if necessary.

In older men, quinolones are the usual initial treatment but if there is evidence of systemic sepsis, then intravenous antibiotics directed at urinary pathogens may be valuable. If an organism is isolated from the urine, this simplifies the choice of antibiotic.

All patients should drink plenty of fluid. Local measures including scrotal support and analgesia are helpful. Antibiotic treatment should continue for at least 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary.

Chronic disease

Chronic non-tuberculous epididymitis usually follows the failure of resolution of an acute episode of epididymitis. Patients typically complain of intermittent episodes of discomfort and the epididymis feels thickened and tender. Treatment involves use of antibiotics (usually quinolones or doxycycline) and anti-inflammatory agents for 4–6 weeks. Epididymectomy or orchidectomy can be considered if there is no resolution although some patients continue to suffer from pain despite such surgery (Summary box 79.8).

Summary box 79.8**Acute epididymo-orchitis**

- In young men usually arises secondary to a sexually transmitted genital infection
- In older men usually arises secondary to urinary infection
- May be a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

TUBERCULOUS EPIDIDYMO-ORCHITIS

Chronic tuberculous epididymo-orchitis usually begins insidiously. The frequency with which the lower pole of the epididymis is involved first indicates that the infection is retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm, uncomfortable discrete swelling of the lower pole of the epididymis. The disease progresses until the

Figure 79.13 Ultrasound of an epididymal cyst.

whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocele in 30 per cent of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicles feel indurated and swollen. In neglected cases, a tuberculous 'cold' abscess forms, which may discharge. The body of the testis may be uninvolved for years, but the contralateral epididymis often becomes diseased. In two-thirds of cases, there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. A chest x-ray should be performed as should imaging of the upper urinary tract. Ultrasound will demonstrate a thickened epididymis.

Treatment

Secondary tuberculous epididymitis may resolve when the primary focus is treated.

Treatment with anti-tuberculous drugs is less effective in genital tuberculosis than in urinary tuberculosis. If resolution does not occur within two months, epididymectomy or orchidectomy is advisable. A course of anti-tuberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

ORCHITIS

Mumps orchitis, which is the most common form of orchitis, develops in 20–30 per cent of post-pubertal patients with a mumps virus infection and it usually develops as the parotid swelling is waning. Evidence of IgM antibodies in the serum supports the diagnosis. The main complication is testicular atrophy, which may cause infertility if the condition is bilateral. Partial testicular atrophy is associated with persistent testicular pain.

Syphilitic orchitis is now uncommon. It can cause bilateral orchitis (which is a feature of congenital syphilis), interstitial fibrosis, which causes painless destruction of the testis or rarely it may lead to a gumma of the testis, which presents as a unilateral slowly growing painless swelling. The latter presentation may be difficult to distinguish from a neoplasm without surgical exploration. Diagnosis is confirmed by serology.

TUMOURS OF THE TESTES

Testicular cancer represents around 1–1.5 per cent of male neoplasms and there is clear evidence of an increased incidence of these tumours in the past 30 years. The vast majority are germ cell tumours and the peak incidence of seminomas is in the fourth decade of life with the non-seminomatous germ cell tumours being more common in the third decade of life. They are the most common form of tumour in young men. Risk factors include a history of testicular maldescent, a history of a contralateral testicular tumour and Klinefelter's syndrome.

Classification and pathology

Tumours of the testis are classified according to their predominant cellular type:

- germ cell tumours (90–95% per cent) (these include seminoma, embryonal cell carcinoma, yolk sac tumor, teratoma, and choriocarcinoma);

- interstitial tumours (1–2 per cent) (these include Leydig cell tumours);
- lymphoma (3–7 per cent);
- other tumours (1–2 per cent).

Seminoma

A seminoma typically has a cut surface which is homogeneous and pinkish cream in colour. It appears to compress neighbouring testicular tissue (Figure 79.14). It consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis. There are two histological variants, one with a more anaplastic appearance and another that is characterised by cells which closely resemble different phases of maturing spermatogonia (spermatocytic seminoma).

Seminomas metastasise mainly via the lymphatics (Figure 79.15) and haematogenous spread is uncommon. The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessels. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved.

Non-seminomatous germ cell tumours (NSGCT)

These tumours may be tiny but can reach the size of a coconut. The smaller tumours may not even distort the tunica albuginea (Figure 79.16). The usual type of teratoma is yellowish in colour with cystic spaces containing gelatinous fluid (Figure 79.17). There are a number of histological types of non-seminomatous germ cell tumours (NSGCT), which may coexist within a single tumour:

- **Embryonal carcinoma.** Highly malignant tumours that occasionally invade cord structures.
- **Yolk sac tumour.** Tumours with this component secrete alpha fetoprotein (AFP).
- **Choriocarcinoma.** Often produces human chorionic gonadotrophin (HCG). This is a highly malignant tumour that metastasizes early via both the lymphatics and the bloodstream.
- **Teratoma.** These tumours contain more than one cell type with components derived from ectoderm, endoderm, and mesoderm. Tumours may range from 'mature' with

Figure 79.14 Seminoma of the testis.

well-differentiated tissue elements to 'immature' with undifferentiated primitive tissues. All can metastasise.

Interstitial cell tumours

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises. They are typically small well circumscribed tumours with a yellow cut surface. Microscopically, the cells are usually uniform and closely packed. Approximately 10 per cent are malignant.

Most prepubertal tumours (which account for around 25 per cent of cases) produce androgens, which cause sexual precocity including prominent external genitalia, suprapubic hair growth and a deep masculinised voice. Regression of the symptoms after orchidectomy may be incomplete. Most post-pubertal interstitial cell tumours produce feminising hormones leading to gynaecomastia, erectile dysfunction, loss of libido and azoospermia.

Clinical features

Usually the patient presents with a painless testicular lump. A sensation of heaviness can occur if the testis is two or three times its normal size, but only a minority of patients experience pain. In a few cases, an episode of trauma calls attention to the swelling. Some cases may simulate epididymo-orchitis and rarely some patients present with severe pain and acute enlargement of the testis because of haemorrhage into the tumour. Such cases can occasionally mimic testicular torsion.

Rarely, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be so tiny that it can be detected only by ultrasonography (Figure 79.16).

On examination, there is an intratesticular solid mass. If present, a lax secondary hydrocele does not usually obscure the underlying tumour. The epididymis becomes more difficult to feel when it is flattened or incorporated in the growth. The vas is never thickened and rectal examination is normal. Around 5 per cent of cases have gynaecomastia (mainly the NSGCT). Metastatic disease is rarely apparent clinically and is more usu-

Figure 79.16 Ultrasound of a small intratesticular tumour with minimal distortion of the tunica albuginea.

ally identified by formal staging investigations. In 1–2 per cent of cases, the tumour is bilateral at the time of diagnosis.

Investigation and staging

The diagnosis is confirmed by ultrasound scanning of the testis (Figure 79.18) which is also able to assess the contralateral testis. It is a mandatory test in all suspected cases of testicular tumour.

In confirmed cases, staging is an essential step in planning treatment. Blood is taken prior to orchidectomy to measure the levels of tumour markers which are raised in around 50 per cent of cases. A rise in AFP is seen in around 50–70 per cent

Figure 79.15 Lymphatic drainage of the testes to para-aortic lymph nodes.

Figure 79.17 Teratoma of the testis – note the solid and cystic areas (courtesy of Dr Keith Simpson, London).

of NSGCTs and a rise in HCG is seen in 40–60 per cent of NSGCTs and around 30 per cent of seminomas. When raised, these markers are used to monitor the response to treatment. The mean serum half-lives of AFP and HCG are 5–7 days and 2–3 days, respectively, and reassessment of the markers following orchidectomy can indicate whether all the tumour tissue has been removed.

While a chest x-ray will occasionally demonstrate the ‘classical’ cannon ball metastases (Figure 79.19), computed tomography (CT) of chest and abdomen has taken over as the most useful means of detecting metastatic disease and for monitoring the response to therapy. Such imaging is usually undertaken after the affected testis has been removed.

Staging of testicular tumours

While TNM staging is the most widely used system for the staging of testicular cancer, the older staging system of stages 1–IV is still considered valuable in determining the treatment options:

The stages are:

- Stage I: the tumour is confined to the testis;
- Stage II: nodal disease is present but is confined to nodes below the diaphragm;
- Stage III: nodal disease is present above the diaphragm;
- Stage IV: nonlymphatic metastatic disease (most typically within the lungs) (Summary box 79.9).

Summary box 79.9

Testicular tumours

- A solid testicular lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the para-aortic lymph nodes
- Ultrasound is a mandatory investigation in all cases of suspected testicular tumour
- Tumour markers (AFP and HCG) should be measured prior to orchidectomy

Treatment

Scrotal exploration and orchidectomy for suspected testicular tumour

The orchidectomy is undertaken via an inguinal incision. The spermatic cord is displayed by dividing the external oblique aponeurosis and a soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. If necessary, the testis should be bisected along its anterior convexity to examine its internal structure. If there is a tumour, the cord should be double transfixed and divided at the level of the internal inguinal ring and the testis removed.

Management by staging and histological diagnosis (after orchidectomy)

The treatment of patients with testicular tumours is usually successful, even in cases that are advanced at presentation. This largely reflects the excellent response of these tumours to platinum-based chemotherapy and (for seminomatous tumours) to radiotherapy. Indeed in recent years the emphasis of clinical trials has been focused upon the identification of those patients who do not need chemotherapy, and who therefore will escape the side effects of treatment.

Stage I tumours

Seminomas are radiosensitive and for many years adjuvant radiotherapy to the para-aortic nodes was the mainstay of treatment for stage I disease. Some years ago, the excellent response to platinum-based chemotherapy led to chemotherapy being introduced for most men with stage 1 seminoma. However, current practice uses CT and tumour marker-based surveillance protocols with chemotherapy being reserved for men who demonstrate relapse.

NSGCTs are not radiosensitive, but they are highly sensitive to combination chemotherapy with bleomycin, etoposide and cis-platinum (so called BEP chemotherapy). Some good prognosis NSGCTs can be managed by surveillance protocols (using regular CT scanning and tumour marker measurement) with the more high risk cases receiving chemotherapy.

Figure 79.18 Testicular ultrasound: the homogeneous tissue of the testicular teratoma on the left of the image produces multiple ultrasound reflections.

Figure 79.19 Cannon ball metastases from carcinoma of the testis.

Stage II–IV tumours

Combination BEP chemotherapy is the mainstay of treatment for stages II–IV seminoma and NSGCT. Retroperitoneal lymph node dissection is sometimes needed in some cases of NSGCT when retroperitoneal masses remain after chemotherapy (Figure 79.20). The tissue removed may contain only necrotic tissue, but some patients have foci of mature teratoma or active malignancy. The operation can be formidable if the tumour mass is large, and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

Prognosis

The prognosis of testicular tumours depends on several factors including the histological type and the stage at presentation. For seminoma, if there are no metastases, 90–95 per cent of patients will be alive five years after diagnosis. If there are poor prognostic features, the survival rate drops to around 70 per cent. For NSGCTs, a five-year survival rate of more than 90 per cent is achievable in patients with good prognosis tumours while for more advanced tumours the five-year survival rate is about 60 per cent (Summary box 79.10).

Summary box 79.10

Testis tumour staging and treatment

- Tumour markers help to make the diagnosis and to follow the response to treatment
- CT scanning of chest and abdomen is central to the staging of testicular tumours
- Testicular tumours are extremely sensitive to platinum-based chemotherapy
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

TESTICULAR TUMOURS IN CHILDREN

These are usually anaplastic teratomas. They occur before the age of three years and are often rapidly fatal.

Figure 79.20 Computed tomography scan showing a large residual retroperitoneal mass after chemotherapy.

TUMOURS OF THE EPIDIDYMISS

These may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a non-cystic lump in the epididymis.

THE SCROTUM

Fournier's gangrene

Fournier's gangrene is an uncommon and nasty condition (Figure 79.21) of infective origin that is characterised by sudden scrotal inflammation, with rapid onset of gangrene leading to exposure of the scrotal contents. Although it can occur in conjunction with sepsis of the testis, epididymis or perianal region, an obvious cause is absent in over half the cases. It can arise following minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess. Many patients have concurrent illnesses that diminish their defences, most notably diabetes mellitus and alcoholism.

There is a mixed infection of aerobic and anaerobic bacteria in a fulminating inflammation of the subcutaneous tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin which in turn results in gangrene. The condition can spread rapidly to involve the fascia and skin of the penis, perineum and abdominal wall.

Clinical features

There is sudden pain in the scrotum associated with prostration, pallor and pyrexia. Cellulitis spreads rapidly (within hours) and progresses to necrosis until the entire scrotal and penile coverings slough, leaving the testes exposed but healthy.

Treatment

Treatment of a case of Fournier's gangrene is a surgical emergency. Urgent wide surgical excision of the dead and infected tissue is essential. This should be accompanied by intravenous antibiotics. Supportive care is essential, because the patients often become severely septic. Early review of the wounds is helpful to confirm that all dead tissue has been removed, and if the patient survives the acute episode, skin grafting is often necessary. Despite best therapy, mortality rates as high as 50 per cent are often reported (Summary box 79.11).

Summary box 79.11

Fournier's gangrene

- Fournier's gangrene requires early and aggressive treatment if the patient is to survive
- Treatment involves urgent surgical debridement of necrotic tissue in combination with intravenous antibiotics

Filarial elephantiasis of the scrotum

Filarial elephantiasis of the scrotum is caused by obstruction of the pelvic lymphatics by worms of which *Wuchereria bancrofti* accounts for 90 per cent of cases. The condition is common in the tropics and is transmitted by mosquitoes. It is often

Figure 79.21 Fournier's gangrene with an area of necrotic skin overlying an area of scrotal inflammation.

accompanied by superadded infection and lymphangitis, resulting in swelling of the genital skin and skin of the lower limbs. In longstanding cases, the enormously swollen scrotum may bury the penis (Figure 79.22). Associated symptoms and signs include fever, epididymitis, hydrocele and chyluria. The diagnosis is usually made clinically, although immunological testing can be helpful.

Medical treatment involves the use of diethylcarbamazine (DEC), ivermectin and albendazole, with the exact regime depending upon geographical location. Surgical treatment is rarely helpful, although a range of procedures has been devised to remove redundant skin and to reconstruct the enlarged scrotum.

Non-filarial elephantiasis

Elephantiasis can occur in the absence of filariasis, most notably in sub-Saharan Africa. Non-filarial elephantiasis can result from fibrosis of the lymphatics caused by lymphogranuloma venereum, but in many cases it is thought to arise as a consequence of persistent contact with irritant soils.

Sebaceous cysts

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (Figure 79.23).

Carcinoma of the scrotum

Chimney sweeps cancer was the first reported occupational cancer (described by Percival Pott in 1775). It is a rare cancer that has also been seen in other workers who come into contact with oil and coal products. Animal studies suggest that aromatic cyclic hydrocarbons are the aetiological factor. Nowadays, this tumour is rarely associated with any obvious aetiological factor. Unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

The growth starts as a wart or ulcer (Figure 79.24) and as it grows it may involve the testis. The tumour should be excised

Figure 79.22 Elephantiasis of the scrotum burying the penis (courtesy of Mr S Bhattacharjee, Lucknow, India).

with a margin of healthy skin. The management of the inguinal nodes parallels the management of penile cancer and if nodal enlargement does not settle with antibiotics following treatment of the primary, then a bilateral groin dissection is indicated.

MALE FACTOR INFERTILITY

For couples of unknown fertility status, approximately 15 per cent are unable to achieve a pregnancy within one year. The inability to conceive may be due to female factor infertility, male factor infertility or a combination of these two factors and approximately 20 per cent of cases of infertility are caused entirely by the male factor.

Aetiology

The two main causes of male factor infertility are testicular causes and vasal or epididymal obstruction. A few cases reflect endocrinological abnormalities, such as hypogonadism or hyperprolactinaemia.

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK, described the 'Puffy tumour' in 1760. In 1756 he sustained a broken leg after a fall from his horse. As he lay on the ground, he sent a servant to buy a door which acted as a stretcher. While his surgeons were contemplating amputating his leg, he persuaded them to splint the leg instead as a result of which he recovered completely. Although some think that Pott's fracture of the ankle was described after this injury of his, it is not so. He sustained a compound fracture of the femur. Nevertheless, history can be controversial. Other authorities feel that Pott actually suffered a fracture-dislocation of the ankle from whence the fracture gets its name. Pott was the first to link an environmental factor to the aetiology of cancer when he demonstrated that chimney sweeps developed squamous cell scrotal cancer. In those days, the chimney sweep's apprentice climbed up inside the chimney.

Figure 79.23 Sebaceous cysts of the scrotum (courtesy of Dr R Kaje MS, Jipmer, India).

Testicular causes include chromosomal problems (e.g. Klinefelter's syndrome), microdeletions of the Y chromosome, cryptorchidism, mumps orchitis, drugs and radiation damage. In most cases, however, the cause is unclear. In these cases, there may be reduced numbers of sperm in the ejaculate (oligozoospermia) or a complete absence of sperm in the ejaculate (azoospermia). Obstructive causes include congenital absence of the vasa (often in association with cystic fibrosis), surgical damage to the vasa, epididymitis and azoospermia is inevitable in these cases.

Assessment and investigation

Given the interplay between male and female factors, the man should not be investigated in isolation from his female partner. A careful history is the mainstay of the assessment with a careful search for aetiological factors. Physical examination is usually normal, but occasionally the testes may feel small (suggestive of a testicular cause), the vasa may be absent, there may be evidence of endocrine abnormalities (gynaecomastia or abnormal hair distribution) or there may be a varicocele. The relation of any varicocele to the infertility is controversial and treatment is not usually indicated.

The female should also be assessed. It is important to remember that female fertility declines from the age of 35 years in a way

Figure 79.24 Carcinoma of the scrotum with bilateral enlargement of the inguinal lymph nodes (courtesy of Department of Medical Photography, Cardiff Royal Infirmary, Cardiff, UK).

that is not true of men. The age of the female is therefore important and the regularity of menstruation should be confirmed either by temperature testing or by endocrinological testing.

The assessment of the male includes semen analysis, which should be tested within 2 hours of the semen being produced. Two or three samples should be tested. The volume of the ejaculate, the numbers of sperm, their motility and the percentage of abnormal or damaged sperm are all predictive of the male fertility. An endocrine screen should be performed including serum testosterone, prolactin, FSH and LH.

Treatment

Sperm counts of less than 20 million sperm per mL are defined as oligozoospermia. If there is a reversible cause, it should be treated. However, in many cases, some form of assisted conception is required.

Azoospermia (the complete absence of sperm from the ejaculate) is either due to obstruction of the pathway of spermatozoa from the testis to the ejaculatory ducts or due to severe testicular failure. In the latter, the serum FSH is typically raised, while in obstructive cases, the FSH is typically normal. If there is doubt as to the cause, then testicular biopsy is mandated to check for the presence of spermatogenesis combined with vasography to assess the presence and location of any obstructive lesion. If the site of the obstruction can be identified, it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

Assisted conception including *in vitro* fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) has revolutionised the management of male factor infertility regardless of the cause of the problem. In ICSI, spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy, can be injected *in vitro* into ova obtained from the mother. Embryos are then transferred into the mother's uterus at the four- to six-cell stage (Summary box 79.12).

Vasectomy for sterilisation

Vasectomy for sterilisation is a common and effective contraceptive procedure. It should be undertaken only after the couple has been carefully counselled. Both partners need to know that the operation is performed to make the man permanently

Summary box 79.12**Male infertility**

- Atrophy of the testis is associated with raised levels of FSH in the blood
- Testicular biopsy will show whether azoospermia is a result of obstruction or failure of sperm production
- If spermatozoa can be harvested they can be used in ICSI with a fertility rate of around 30 per cent

sterile. They should be warned that normal contraceptive precautions should continue until the success of the operation is confirmed by semen analysis performed 12–16 weeks after surgery. They should also be warned of the possibility of spontaneous recanalisation, which may restore fertility unexpectedly and of the possibility of chronic testicular pain which may occur in up to 5 per cent of men.

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral scrotal incisions or through a single midline scrotal incision. For medico-legal reasons, it is wise to remove a segment of each vas to prove that it has been successfully divided. Burying the cut ends or turning them back on themselves helps to prevent them rejoining.

Reversal of vasectomy may not restore fertility even if technically successful because of damage to the testis secondary to the vasectomy. Although patency rates of 80 per cent or more are commonly reported, successful fertility rates are much lower and diminish with increasing delay from the time of vasectomy (Summary box 79.13).

Summary box 79.13**Vasectomy**

Counselling before vasectomy should include mention that:

- The operation is not immediately effective and that contraceptive precautions should be continued until there have been two negative semen analyses
- The procedure should be considered irreversible
- Spontaneous recanalisation is rare, but can occur
- There is a risk of chronic scrotal pain postoperatively

LEARNING OBJECTIVES

To understand:

- Pelvic anatomy and reproductive physiology
- The common causes of vaginal bleeding and acute pain in early pregnancy
- The surgical management of acute pelvic inflammatory disease, endometriosis, uterine fibroids and ovarian tumours

ANATOMY

The female external genitalia are described as the vulva, which is bordered by the mons veneris anteriorly and the labiocrural folds posterolaterally. The introitus tends to be open in parous women, but otherwise appears closed by the apposing labia majora. The labia minora are folds of skin that fuse anteriorly to form the clitoris, which contains erectile tissue similar to the penis. The fourchette is the posterior part of the introitus, which must stretch considerably to allow the delivery of a baby.

The vagina is an elastic, distensible tube, approximately 10 cm long, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (Figure 80.1).

The uterus, consisting of a body and a cervix, is a pear-shaped structure that is flattened anteroposteriorly giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) consisting of condensed connective tissue. The cervix is a canal, approximately 2 cm long, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The length of the uterine cavity, including the cervical canal, is approximately 6 cm in nulliparous women and approximately 8 cm in parous women. The walls of the uterus are 1–2 cm thick and composed of muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones (see below under Reproductive physiology).

At the uterine fundus, on either side, are the cornua by which the uterus is connected to each Fallopian tube. These are thin, muscular tubes, approximately 10 cm long, which connect the

peritoneal and uterine cavities. They are divided into four parts: intramural, isthmus, ampulla and fimbriated opening, which pick up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but they widen in the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels and the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm long, suspended from the back of the broad ligament on either side of the pelvis. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligaments to the pelvic brim on either side.

Figure 80.1 Female anatomy.

The cervix is located in the centre of the bony cavity of the pelvis and the uterus can be pivoted around this point. It is usually angled forwards (anteverted) at approximately 90° relative to the vagina. It is usually freely mobile but filling of the bladder or changes in position may rotate it backwards. In some women, the uterus is retroverted, either because of weak ligaments or because the uterus becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forward (anteflexed) relative to the cervix when anteverted or backwards (retroflexed) when retroverted, in which case it can usually be felt in the pouch of Douglas on vaginal examination. The most common cause of an enlarged uterus, aside from pregnancy, is the presence of fibroids (benign tumours of the myometrium) growing inside or outside the uterus. When fibroids are present, the overall size of the uterus is described in terms of weeks of pregnancy as it expands forwards and upwards into the abdominal cavity with increasing gestational age.

REPRODUCTIVE PHYSIOLOGY

The menstrual cycle is under the control of circulating hormones produced within the hypothalamic–pituitary–ovarian axis. Thus, gonadotrophin-releasing hormone (GnRH) produced in the hypothalamus stimulates the pituitary to produce follicle stimulating hormone (FSH) and luteinising hormone (LH), which in turn control how the ovary produces an oocyte on a monthly basis and also the hormones oestrogen and progesterone. These hormones have an effect on many structures in the body, but principally on the endometrium, which prepares itself to receive a fertilised egg during the course of the menstrual cycle. In the first half (proliferative or follicular phase) of the cycle, following menstruation, the endometrium starts to regrow or proliferate in response to oestrogen produced by the growing ovarian follicle. The endometrium becomes thick and spongy during this phase of the cycle, associated with considerable angiogenesis.

Ovulation occurs at mid-cycle, on approximately day 14 (day 1 of the cycle is defined as the first day of menstruation), following which the follicle is transformed into the corpus luteum. In the second half (secretory or luteal phase) of the cycle, the endometrium thickens even more in response to the hormone progesterone, produced by the corpus luteum (Figure 80.2).

If fertilisation occurs, the fertilised egg is transported along a Fallopian tube into the uterine cavity and then implants in the endometrium. If fertilisation does not occur or if the fertilised

egg fails to implant, the endometrium is shed and menstruation occurs. Bleeding (a 'period') tends to last for 4 days, but can range from 2–6 days. Typically, about 40 mL of blood is lost during each period; if the bleeding is heavy (i.e. greater than 80 mL), blood clots may form. The whole process then starts again in the next menstrual cycle.

If fertilisation does occur, the duration of the pregnancy (gestational age) is traditionally calculated from the first day of the last menstrual period (LMP); however, ovulation may occur earlier or considerably later than day 14 or the woman's recollection of the date of the LMP may be incorrect, which means that calculating gestational age on the basis of the LMP alone may be inaccurate. This explains the alternative practice of calculating gestational age using ultrasound measurements of fetal size.

VAGINAL BLEEDING IN EARLY PREGNANCY

A miscarriage is defined as the spontaneous loss of an intrauterine pregnancy at less than 24 weeks' gestation. A miscarriage usually starts with painless vaginal bleeding, at which point it is defined as a threatened miscarriage. The bleeding may then become heavier with associated uterine cramps, at which point it becomes an inevitable miscarriage. Blood clots and products of conception (i.e. fetal and placental tissue) are passed through the cervical os until the uterus is emptied (defined as a complete miscarriage). Sometimes, not all the products of conception are passed spontaneously (defined as an incomplete miscarriage) and the woman may require an evacuation of retained products of conception (ERPC) to remove what is left of the pregnancy. The operation involves passing a plastic suction curette through the cervix into the uterine cavity. The current (2006) Royal College of Obstetricians and Gynaecologists (RCOG) recommendations are for ERPC to be considered if there is persistent excessive bleeding, haemodynamic instability, evidence of infected retained tissue or suspected gestational trophoblastic disease. Serious operative complications, which are fortunately rare, include uterine perforation with, possibly, intra-abdominal trauma (e.g. bowel damage), cervical tears and haemorrhage.

In the case of a miscarriage, on vaginal examination there is typically no cervical excitation (pain on moving the cervix) or tenderness in the vaginal fornices, which are signs associated with an ectopic pregnancy. The uterus feels the right size or smaller for the gestational age. The internal cervical os, by definition, is closed if the miscarriage is threatened or complete and open if the miscarriage is inevitable or incomplete. If the fetus has not developed (defined as a missed abortion) the uterus will feel small for the gestational age and there may have been no bleeding, in which case the os will be closed. In such circumstances, the os will need to be dilated before performing the ERPC.

An ultrasound scan is usually performed to determine whether there is a viable intrauterine pregnancy present. It may not be possible to determine the precise location of the pregnancy because the woman has had a complete miscarriage, the pregnancy is not sufficiently advanced or she has an ectopic pregnancy that is not visible on ultrasound. For these reasons, it is important to establish the gestational age as accurately as possible, on the basis of the LMP and the length/regularity of the menstrual cycle, as well as with any other relevant information, e.g. fertility treatment. It is still not uncommon, especially in

Figure 80.2 Endocrine cycle. E₂, oestrogen; FSH, follicle-stimulating hormone; LH, luteinising hormone; P, progesterone.

early pregnancy, to make the diagnosis of a miscarriage on clinical grounds alone, for example in the case of:

- heavy vaginal bleeding with clots and associated uterine cramps;
- no history of abdominal pain;
- no cervical excitation or tenderness in the vaginal fornices;
- no risk factors for an ectopic pregnancy, e.g. a past history of pelvic inflammatory disease (PID) or previous tubal surgery.

Vaginal bleeding in early pregnancy may also result from a local cause such as a cervical lesion (which may first manifest as bleeding after intercourse) or, rarely, trauma.

VAGINAL BLEEDING IN THE NON-PREGNANT STATE

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding) or after intercourse (post-coital bleeding). It may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an intrauterine contraceptive device (IUCD). The principal causes of these types of bleeding are shown in Table 80.1.

The mainstay of management is to identify and treat pathology (except in women <40 years old with heavy, menstrual periods in whom pathology is very rarely found; these women tend to be treated symptomatically). This usually involves ultrasound examination and an endometrial biopsy, either under direct vision at hysteroscopy or blindly with a Pipelle. The indications for endometrial biopsy are shown in Summary box 80.1.

Summary box 80.1

Indications for endometrial biopsy

Endometrial biopsy should be considered in the following women:

- All women >40 years old with excessively heavy, irregular or frequent bleeding
- Younger women with major risk factors for endometrial hyperplasia/cancer:
 - Polycystic ovarian syndrome
 - Obesity
 - Tamoxifen treatment
- Unopposed oestrogen therapy
- Family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer (Lynch syndrome)
- Younger women who fail to respond to conventional treatment

Women taking tamoxifen – the selective oestrogen receptor modulator used in breast cancer treatment – represent a special group because the drug can induce endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after one to two years of treatment and a quadrupling after five years. The relationship is time-dependent and dose-independent and the risk does not decrease after stopping treatment. There is no clear consensus regarding the need for screening and which method to use; the alternative, more common, approach is to investigate only those women

Table 80.1 Causes of vaginal bleeding in the non-pregnant state.

Menstrual	Endometrial polyp/malignancy ^a Fibroids

Post-coital	Vaginal malignancy ^a Cervical ectropion/polyp/malignancy

^aThese cancers occur principally in post-menopausal women.

who develop post-menopausal bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane, which are also used in the treatment of breast cancer but whose effects are not mediated via the oestrogen receptor, are associated with less endometrial pathology than tamoxifen and it has even been suggested that aromatase inhibitors may reverse abnormalities induced by tamoxifen.

Women with hereditary non-polyposis colorectal cancer (HNPCC) (Lynch syndrome) and those who are at high risk of developing HNPCC are another special group, as the lifetime risk of developing endometrial cancer is as high as 60 per cent. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in HNPCC patients is the fifth decade. However, it appears that five-year survival rates in HNPCC patients with endometrial cancer are similar to those in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 years with transvaginal ultrasound, to measure endometrial thickness and look for polyps, and with endometrial biopsy.

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. Medical treatments used to reduce the amount of menstrual loss include tranexamic acid, mefenamic acid and the combined oral contraceptive (COC). It may be necessary to stop the bleeding completely using high-dose progestagens, the COC taken continuously or a GnRH agonist, which induces a menopause-like state. Increasingly, an intrauterine system (IUS) similar to a conventional coil, which releases levonorgestrel, is offered to patients as an alternative; it has the added advantage of being a reliable contraceptive.

The surgical treatments for excessive bleeding and their principal operative complications are described in Table 80.2; they are divided into those procedures that retain the uterus and those that do not. The ovaries may or may not be removed at the same time depending upon the woman's age and any coexisting pathology. The aim of all of the ablation methods is to reduce menstrual bleeding by ablating the endometrial layer and some of the underlying myometrium using electrical, thermal or laser energy. Amenorrhoea is not guaranteed, but the procedures are less invasive and costly than hysterectomy. Clearly, none of these surgical treatments is suitable for women who wish to conceive.

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state – cervical intraepithelial neoplasia (CIN) – using cervical cytology. In the UK, this is carried out every three to five years in women

aged between 25 and 65 years. Infection with certain human papillomavirus (HPV) serotypes (16, 18, 31 and 33) is associated with an increased risk of invasive disease. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryocautery, cold coagulation, electrodiathermy or laser) or excision (large loop excision of the transformation zone (LLETZ)). However, it is very likely that the incidence of CIN will decrease steadily in the future as a result of vaccination against HPV in young girls and HPV testing.

ACUTE PELVIC PAIN IN EARLY PREGNANCY

Ectopic pregnancy

An ectopic pregnancy is one that grows outside the uterine cavity, almost always in a Fallopian tube (rare sites include the ovary, cervix and broad ligament). As the ectopic grows, the placenta infiltrates blood vessels within the Fallopian tube, which can cause bleeding within the tube and bleeding into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the Fallopian tube causing substantial intraperitoneal blood loss. It is the most common cause of maternal death in the first trimester and accounts for 9 per cent of maternal deaths in the UK. The major risk factors for ectopic pregnancy are shown in Summary box 80.2.

Summary box 80.2

Risk factors for ectopic pregnancy

- Previous pelvic inflammatory disease
- Smoking
- Older age
- Previous spontaneous miscarriage
- Previous medical termination
- History of infertility
- Previous use of an intrauterine contraceptive device

An ectopic pregnancy may be suspected on clinical grounds, but making the diagnosis can be difficult because the presentation is so variable and can mimic that of a miscarriage (Summary box 80.3).

Summary box 80.3

Differential diagnoses for acute pain in early pregnancy

- Ectopic pregnancy
- Miscarriage
- Urinary tract infection
- Ovarian accident
- Pain unrelated to pregnancy, e.g. acute appendicitis

There may be a history of lower abdominal pain with a small amount of vaginal bleeding at 4–6 weeks' gestation. On vaginal examination, there may be cervical excitation and tenderness in

Figure 80.3 Laparoscopy showing an ectopic pregnancy.

the vaginal fornices; the cervical os is closed. Alternatively, the woman may not have any symptoms or physical findings. The urinary pregnancy test is usually positive. Modern monoclonal antibody-based urine tests can detect the beta subunit of human chorionic gonadotropin (β -hCG) at levels of 25 IU/L, which are reached 9 days post-conception, i.e. on day 23 of the menstrual cycle assuming ovulation occurred on day 14.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected. The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound in the uterus. An ectopic pregnancy is more likely if fluid is seen in the pelvis or an adnexal mass is seen on ultrasound.

In equivocal cases, measuring serum levels of β -hCG can help to establish the diagnosis. β -hCG levels double every 48 hours if the pregnancy is viable and intrauterine. Levels tend to be static or the rise is less than double over a 48-hour period if the pregnancy is ectopic. A single level above approximately 1500 IU/L in association with an empty uterus on ultrasound is highly suggestive of an ectopic pregnancy. The best diagnostic test is laparoscopy (Figure 80.3); occasionally, however, if the pregnancy is not sufficiently advanced, the ectopic pregnancy is too small to be seen in the Fallopian tube. There is also a view that a laparoscopy should only be performed once a miscarriage has been excluded because of the surgical and anaesthetic risks associated with the procedure.

Once an ectopic pregnancy has been diagnosed at laparoscopy, a salpingectomy is usually performed. A salpingostomy may be performed instead as some gynaecologists maintain that subsequent intrauterine pregnancy rates are higher and recurrent ectopic rates lower following conservative surgery. Laparoscopy is the preferred approach because it is associated with shorter operation times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates.

In practice, the type of operation chosen depends on factors such as the following:

- **The amount of bleeding.** An immediate laparotomy may be required if the woman has lost a great deal of blood.

Table 80.2 Surgical treatments for excessive vaginal bleeding.

Treatment	Route	Major operative risks
Removal of uterus: hysterectomy		
Subtotal (cervix retained)	Abdominal; laparoscopic	Damage to ureter, bladder or bowel; may result in fistula; risks of laparoscopy
Total (cervix removed)	Abdominal; vaginal; laparoscopic; laparoscopic-vaginal	
Retention of uterus: endometrial ablation		
Thermal balloon	Device inserted into uterine cavity	Uterine perforation
Cryotherapy	Device inserted into uterine cavity	Uterine perforation
Microwave	Device inserted into uterine cavity	Uterine perforation; thermal damage to pelvic organs (especially bowel)
Transcervical resection of endometrium	Hysteroscopic	Bleeding; fluid overload; uterine perforation; thermal damage to pelvic organs (especially bowel)

- **The state of the tube**, i.e. the size of the ectopic pregnancy and whether or not it has ruptured (in general, if the ectopic pregnancy is too large the chances of conservative surgery being successful are small; if it has ruptured, there is little point in trying to be conservative).
- **The state of the other tube**. One usually tries to be as conservative as possible if the other tube has been affected by PID (i.e. it is closed or densely adherent to other pelvic organs).
- **Previous ectopic pregnancy or tubal surgery**. One usually performs a salpingectomy if a woman has had a previous ectopic pregnancy or tubal surgery in the same tube.
- **The woman's fertility intentions**. One usually performs a salpingectomy if a woman does not want more children.

Sometimes, the ectopic pregnancy is located at the very end of the tube, in which case it may be possible simply to 'milk' it out, thereby conserving the tube. The principal disadvantage of this method (and salpingostomy) is that some residual trophoblastic tissue can be left inside the tube. The tissue often survives and continues to grow, which can cause intra-abdominal bleeding. The best method for determining whether all of the tissue has been removed at surgery is to measure serial serum β -hCG levels, which should fall to zero over time if all the tissue has been removed; β -hCG levels remain constant or rise if there is residual trophoblastic tissue, which may necessitate another laparoscopy to remove the tube.

In the United States, many women avoid surgery altogether by being treated with intramuscular injections of methotrexate, which is toxic to trophoblastic tissue. The drug has some side effects and the treatment carries the risks associated with residual trophoblastic tissue, namely internal bleeding and the eventual need for a laparoscopy. In the UK, methotrexate seems to be used only in those patients who are at increased surgical risk (e.g. the morbidly obese or those with extensive pelvic adhesions).

After treatment, the patient who still has one or both tubes should be warned that she is at increased risk of another ectopic pregnancy. She should therefore be encouraged to present as early as possible in a subsequent pregnancy to rule out this diagnosis.

INFECTION

The overwhelming majority of cases of acute PID are caused by ascending infection, which is usually sexually transmitted. Rarer causes include spread from other pelvic organs, e.g. the appendix. *Chlamydia trachomatis* is the most common organism responsible for PID; the prevalence of *Neisseria gonorrhoeae* varies depending upon the locality. Infection involves the upper genital tract, particularly the endometrium and Fallopian tubes. Risk factors include young age at first sexual activity, a high number of sexual partners and current use of an IUCD; infection may also follow a surgical procedure, e.g. termination of pregnancy.

There are no definitive criteria for the diagnosis of acute PID. Most clinicians rely instead upon the presence of one or more of the following features, which are suggestive of the diagnosis:

- lower abdominal pain and tenderness;
- deep dyspareunia (pain on intercourse);
- abnormal vaginal or cervical discharge;
- cervical excitation and adnexal tenderness;
- fever $>38^{\circ}\text{C}$.

The differential diagnoses include endometriosis, urinary tract infection, appendicitis and gastrointestinal dysfunction. A raised neutrophil count and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) level support the diagnosis. Ultrasound may be useful if there appear to be hydrosalpinges present and/or tubo-ovarian abscesses. All women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis* by taking endocervical with or without urethral swabs. *C. trachomatis* is an intracellular organism; therefore, samples obtained for diagnostic purposes should contain cellular material. It is important to wipe off any discharge before inserting the swab inside the cervical os and firmly rotating it against the endocervix.

The current RCOG (2008) guidelines recommend a low threshold for empirical treatment because the consequences of failing to treat acute PID effectively are so significant. Treatment should commence as soon as samples have been obtained for culture even though the results are unavailable; it should include a broad-spectrum antibiotic against coliforms and anaerobic

species, which are responsible for secondary infection. Contact tracing and treatment, if possible, are essential (Summary box 80.4).

Inadequate or inappropriate treatment is associated with a significant risk of developing infertility, ectopic pregnancy,

Fitz-Hugh–Curtis syndrome (an extrapelvic manifestation of PID associated with right upper quadrant pain, which probably results from inflammation of the liver capsule and diaphragm) and chronic pelvic pain in the future. The risk of infertility is obviously of great concern. Approximately 20 per cent of women treated for PID will become infertile because of tubal damage; >50 per cent of tubal infertility cases are due to *C. trachomatis* although, interestingly, many of these women do not report a history of PID (Summary box 80.5). In total, 6 per cent of women will have an ectopic in the first pregnancy following an episode of acute PID, a figure that is approximately ten times greater than the rate in the general population.

Summary box 80.4

Treatment of pelvic inflammatory disease

- Because of the lack of definitive clinical diagnostic criteria, a low threshold for the empirical treatment of pelvic inflammatory disease (PID) is recommended
- Women with suspected PID should be screened for gonorrhoea and *Chlamydia*. Testing for gonorrhoea should be with an endocervical specimen, tested via culture (direct inoculation on to a culture plate or transport of the swab to the laboratory within 24 hours) or using a nucleic acid amplification test (NAAT). Screening for *Chlamydia* should also be from the endocervix, preferably using a NAAT. Taking an additional sample from the urethra increases the diagnostic yield for gonorrhoea and *Chlamydia*. A first-catch urine sample provides an alternative sample
- Outpatient antibiotic treatment should be commenced as soon as the diagnosis is suspected. Treatment should be based on one of the following regimens:
 - 400 mg oral ofloxacin twice a day plus 400 mg oral metronidazole twice a day for 14 days; or
 - 250 mg intramuscular ceftriaxone immediately or 2 g intramuscular cefoxitin immediately with 1 g oral probenecid, followed by 100 mg oral doxycycline twice a day plus 400 mg metronidazole twice a day for 14 days
- Admission to hospital is appropriate in the following circumstances:
 - surgical emergency cannot be excluded
 - clinically severe disease
 - tubo-ovarian abscess
 - PID in pregnancy
 - lack of response to oral therapy
 - intolerance to oral therapy
- In more severe cases, inpatient antibiotic treatment should be based on intravenous therapy, which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:
 - 2 g intravenous ceftriaxone three times a day plus 100 mg intravenous doxycycline twice a day (oral doxycycline may be used if tolerated), followed by 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day for a total of 14 days; or
 - 900 mg intravenous clindamycin three times a day, plus intravenous gentamicin: 2 mg/kg loading dose followed by 1.5 mg/kg three times a day (a single daily dose of 7 mg/kg may be substituted), followed by 450 mg oral clindamycin four times a day to complete 14 days or 100 mg oral doxycycline twice a day plus 400 mg oral metronidazole twice a day to complete 14 days or 400 mg intravenous ofloxacin twice a day plus 500 mg intravenous metronidazole three times a day for 14 days

Summary box 80.5

Chlamydia and gonorrhoea testing

There is a need to test women (especially those sexually active under the age of 25 years) who present with:

- Purulent vaginal discharge
- Post-coital/intermenstrual bleeding
- Mucopurulent cervicitis
- Inflamed/friable cervix (which may bleed on contact)
- Urethritis
- Suspected pelvic inflammatory disease
- Reactive arthritis

The majority of suspected cases are treated in the community, but hospital admission is advisable if there is doubt about the diagnosis or symptoms/signs are severe. In hospital, antibiotics should be given intravenously until 24 hours after clinical improvement. If there is an IUCD *in situ*, it should be removed with adequate counselling regarding pregnancy risk (if intercourse has occurred recently) and future contraception.

Severe PID manifests as a tubo-ovarian abscess, so named because the Fallopian tube and ovary become blended into a single, pus-filled, inflammatory mass, which is usually adherent to the uterus and surrounding bowel. The infection may have

Figure 80.4 Pelvic inflammatory disease.

progressed from a milder form of PID or, increasingly, it may result from the introduction of infection or bowel damage at transvaginal oocyte aspiration in a patient undergoing *in vitro* fertilisation (IVF). Modern medical practice is to manage tubo-ovarian abscesses (Figure 80.4) conservatively unless the patient fails to respond to intravenous antibiotics and systemic support. The response is judged to be inadequate if the woman remains systemically unwell, her symptoms do not improve, fever is not reduced, the white blood cell count does not fall and there is no evidence on ultrasound of the abscess becoming smaller. In such circumstances, surgical treatment is necessary, i.e. adhesiolysis and drainage of the abscess, at laparotomy or laparoscopy. As most women with a tubo-ovarian abscess are in the reproductive years, the intention is always to be as conservative as possible at surgery. Rarely, however, if the abscess has ruptured (Figure 80.5) and the patient is extremely ill, then hysterectomy and bilateral salpingo-oophorectomy may be necessary.

Abscess drainage under radiological guidance, e.g. a transgluteal approach via the greater sciatic foramen under computed tomography (CT) guidance, is sometimes performed. Transvaginal ultrasound-guided aspiration has also been advocated. It is clearly less invasive and there are claims that the method is as effective as surgery; however, it carries additional risks such as bowel damage.

UTEROVAGINAL PROLAPSE

Congenital weakness of the pelvic floor ligaments and fascia may be found in conditions such as spina bifida and bladder exstrophy. Far more common, however, are the acquired forms of pelvic floor damage caused by prolonged or difficult labour and multiparity. A gradual increase in denervation of the striated muscle of the pelvic floor with age and oestrogen deficiency at the menopause can also occur in nulliparous women (Figure 80.6).

A minor degree of prolapse may be asymptomatic but with more significant degrees the patient complains of 'something coming down'. A cystocele (bladder prolapse) and a cystourethrocele lead to the sensation of a lump in the vagina and may also be associated with incontinence and recurrent urinary infections. Uterine descent can lead to backache; with complete prolapse of the uterus (procidentia) there may be

Figure 80.5 Pelvic inflammatory disease with rupture of a pelvic abscess.

vaginal discharge, ulceration of the vaginal skin and bleeding. A rectocele (prolapse of the rectum into the vagina) may cause difficulties with defaecation or a sensation of incomplete defaecation, which is relieved by digital reduction of the prolapse.

Non-surgical management of uterovaginal prolapse is with physiotherapy, hormone replacement therapy (HRT) and the use of vaginal rings and pessaries. The vinyl ring is inserted between the posterior fornix and the pubic bone. The main complication is vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the ring frequently. The aims of surgical management are usually to correct the prolapse, treat any associated incontinence and preserve coital function if appropriate. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal approach or increasingly by a laparoscopic or minimal access approach with the use of vaginal slings and tapes (Table 80.3).

Milton Lawrence McCall, 1911–1963, Founding Chairman, Department of Obstetrics and Gynecology, Magee-Women's Hospital, Pittsburgh, PA, USA described his suture in 1957. Following his untimely death in 1963, the 'Milton Lawrence Professorship and Chair, Department of Obstetrics and Gynecology and Reproductive Sciences' was established in the University of Pittsburgh, PA, USA.

Table 80.3 Surgical treatments for uterovaginal prolapse.

Condition	Treatment
Urethrocele/cystocele (Figure 80.6a)	Traditionally, an anterior vaginal wall repair (anterior colporrhaphy) was performed vaginally; now replaced by vaginally inserted tape (transvaginal tape (TVT) or transobturator tape (TOT)) or mesh slings
Uterine prolapse (Figure 80.6b)	If family complete, a vaginal hysterectomy with an anterior vaginal wall repair if necessary. If the uterus is to be preserved use either amputation of the cervix with suturing of the transverse cervical ligaments vaginally (Manchester repair) or laparoscopic plication of the uterosacral ligaments (McCall suture)
Enterocoele (Figure 80.6c)	Similar technique to repair of a hernia. The vaginal skin is opened and the hernial sac repaired
Vault prolapse (Figure 80.6d)	Sacrospinous fixation or sacrocolpopexy; the vault is attached to the sacrum using a non-absorbable suture
Rectocele (Figure 80.6e)	Posterior colporrhaphy: the posterior vaginal wall is opened, the rectum returned to its normal position and redundant vaginal skin is excised. A laparoscopic approach to repairing the defect in the pelvic floor with or without the use of a mesh is now more popular and, as there is no resulting scarring in the vaginal skin, the incidence of post-surgery dyspareunia is less

The **Manchester repair** was introduced at St Mary's Hospital for Women and Children, Manchester, UK.

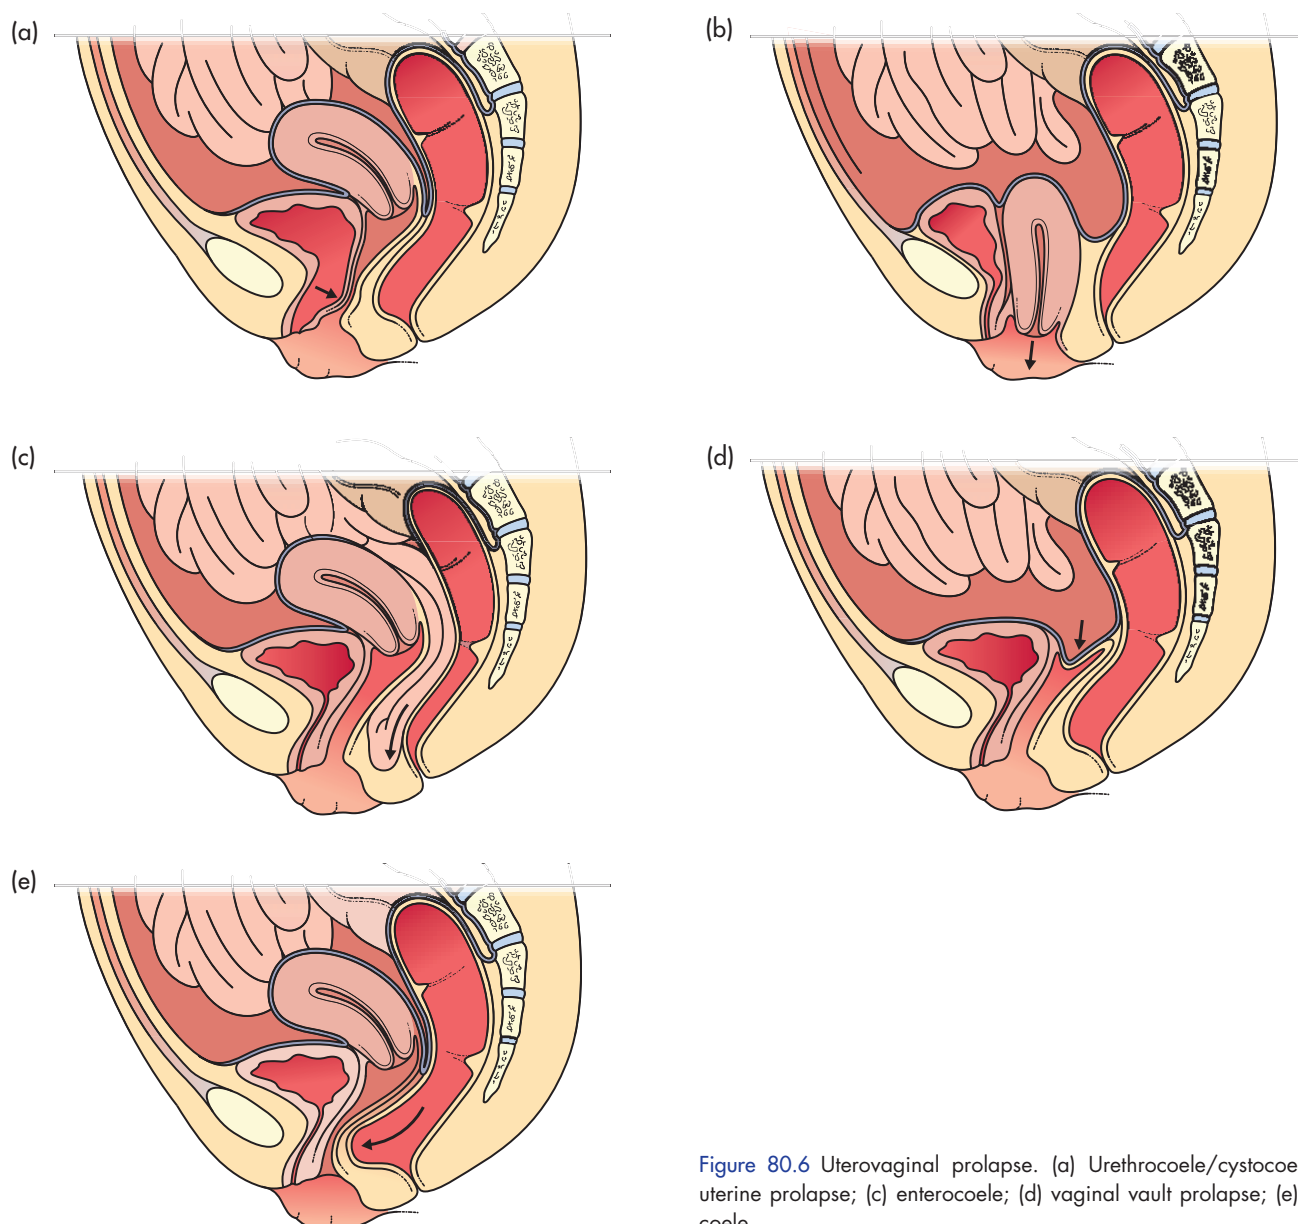

Figure 80.6 Uterovaginal prolapse. (a) Urethrocoele/cystocoele; (b) uterine prolapse; (c) enterocoele; (d) vaginal vault prolapse; (e) rectocoele.

TUMOURS

Uterine fibroids (leiomyomas)

Fibroids are benign, well-circumscribed, smooth muscle tumours of the uterus. Most women will have more than one fibroid, varying in diameter from 1–10 cm, which are typically found in the following locations (Figure 80.7):

- **Subserosal** may cause pressure symptoms (see below); if pedunculated, they can be difficult to distinguish from an ovarian tumour.
- **Intramural** may similarly cause pressure symptoms; associated with infertility and heavy periods.
- **Submucosal** associated with infertility, recurrent pregnancy loss and heavy periods; if pedunculated, may occasionally extrude through the cervical os.
- **Rare sites** include the broad ligament and cervix.

Women with uterine fibroids will present with heavy and/or irregular menstrual bleeding, pressure symptoms or problems conceiving, especially if there is a fibroid in the uterine cavity. The pressure symptoms include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

The diagnosis is usually apparent on bimanual and/or abdominal examination, on the basis of finding an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; as a general rule, the uterus is felt separately on vaginal examination if an ovarian tumour is present, although not if the structures are adherent to each other. Ultrasound can

Figure 80.7 Uterine fibroids.

Figure 80.8 Magnetic resonance imaging of uterine fibroids.

usually distinguish fibroids from ovarian tumours; if not, magnetic resonance imaging (MRI) is clinically useful (Figure 80.8) but, sometimes, it may be necessary to perform a laparoscopy to distinguish between the two pathologies (Figure 80.9).

Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events. Otherwise, the woman has time to consider her treatment options, which include shrinkage of the fibroids by inducing a hypo-oestrogenic state with a GnRH agonist, uterine artery embolisation (UAE), myomectomy (removal of the individual fibroids) and hysterectomy. The choice depends upon the woman's age and fertility intentions, the size and number of fibroids and their location. It is also important to know whether there are fibroids in the uterine cavity, especially if the woman is trying to conceive.

A GnRH agonist will usually shrink fibroids, but this class of drug has the disadvantage that treatment cannot be continued indefinitely because of the associated loss in bone mineral density; in addition, the fibroids tend to regrow to their original size when treatment is discontinued. UAE is becoming increasingly popular as an alternative to surgery. It involves blocking the blood supply to the fibroids using a technique in which particles are embolised into each uterine artery via an angiographic catheter in a similar manner to the well-established technique

Figure 80.9 Laparoscopic view of a fibroid of the uterine fundus.

for treating massive post-partum haemorrhage (Figure 80.10). Following embolisation, the fibroids usually shrink, bringing symptomatic relief, i.e. decreased menstrual bleeding and fewer pressure symptoms. Complications include arterial injury at the site of catheter insertion, severe pain as a result of uterine ischaemia, infection, and ovarian damage and thromboembolism (a small number of deaths have been reported from uterine infection and pulmonary embolism). There is no consensus regarding the suitability of the technique for women who wish to conceive. Numerous pregnancies have been reported in women who have had UAE, but concern still exists regarding the possible adverse effects on myometrial strength and ovarian function, which

Figure 80.10 Pre-embolisation angiogram showing catheterisation of left uterine artery and blood supply to large fundal fibroid. Image courtesy of Dr Mark Bratby, Consultant Vascular and Interventional Radiologist, John Radcliffe Hospital, Oxford, UK.

might affect a woman's chances of conceiving, carrying the pregnancy and delivering normally.

Myomectomy (performed at laparotomy or increasingly at laparoscopy) involves the removal of pedunculated, subserosal and/or intramural fibroids and closure of any defects left in the uterine wall. Surgical complications are unusual; in exceptional circumstances, however, a hysterectomy may be necessary because of uncontrollable blood loss. Fibroids in the uterine cavity should be removed hysteroscopically; the risks of the procedure are similar to those for transcervical resection of the endometrium (TCRE) (see Table 80.2).

Endometriosis

Endometriosis – defined as the presence of endometrial-like tissue in extrauterine sites – is a complex genetic trait that affects up to 10 per cent of women in the reproductive years. The symptoms associated with the disease include severe dysmenorrhoea, chronic pelvic pain, ovulation pain, deep dyspareunia, cyclical symptoms related to the involvement of other organs (e.g. bowel or bladder) with or without abnormal bleeding, infertility and chronic fatigue. However, the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome or interstitial cystitis) and a significant proportion of affected women are asymptomatic.

The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation). The extent of the disease varies from a few, small lesions on otherwise normal pelvic organs to large, ovarian, endometriotic cysts (endometriomas). There can be extensive fibrosis in structures such as the uterosacral ligaments (Figure 80.11) and adhesion formation causing marked distortion of pelvic anatomy (Figure 80.12). Disease severity can be assessed simply by describing the operative findings or, quantitatively, using various classification systems, but there is little correlation between such systems and the type or severity of pain symptoms.

Endometriosis typically appears as superficial 'powder-burn' or

'gunshot' lesions on the ovaries, serosal surfaces and peritoneum – black, dark-brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis (Figure 80.13). Atypical or 'subtle' lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown peritoneal discolouration of the peritoneum. Ovarian endometriomas usually contain thick fluid like tar. They are distinguishable from simple haemorrhagic ovarian cysts because, typically, they are densely adherent to the peritoneum of the ovarian fossa. The surrounding fibrosis may involve the bowel. Deeply infiltrating endometriotic nodules represent another disease type. They extend more than 5 mm beneath the peritoneum and may grow into the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina, they may be visible on speculum examination as 'blue-domed' cystic lesions in the posterior fornix. Lesions infiltrating the bowel may mimic cancer in their presentation.

The diagnosis of endometriosis is usually made on visual inspection of the pelvis at laparoscopy; non-invasive diagnostic tools, such as ultrasound scanning, can reliably detect only severe forms of the disease, i.e. endometriomas. The treatment options are limited because the cause is uncertain; these include hormonal drugs to suppress ovarian function, the levonorgestrel-IUS and surgical ablation of endometriotic lesions. Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that have problematic side effects. Lastly, patients with endometriosis may be at increased risk of ovarian cancer (especially endometrioid and clear-cell types) and non-Hodgkin's lymphoma, which adds to the burden of the disease.

Finding pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. The findings may, however, be normal.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy and removal of all the

Figure 80.11 Endometriosis seen on the uterosacral ligament.

Figure 80.12 Bilateral ovarian endometriosis with pelvic adhesions.

Figure 80.13 Endometriosis seen on the peritoneal surface of the diaphragm.

endometriosis present offers a good chance of cure. However, surgical treatment in a woman who wishes to conceive in the future aims to be as conservative as possible, ensuring in particular that ovarian function is preserved. The aim is to remove all of the endometriotic tissue and restore anatomy to normal by lysing adhesions. The standard (preferably laparoscopic) methods used are ovarian cystectomy and tissue excision or ablation with electrodiathermy, thermal coagulation or laser. The surgical risks include those for any laparoscopic procedure, as well as damage to the ureters and bowel; the risks are increased if deeply infiltrating disease is present, particularly if there is bowel wall involvement. Rarely, infection in an endometrioma will result in the formation of a tubo-ovarian abscess.

Benign ovarian tumour and cysts

Overall, 90 per cent of ovarian tumours are benign, although there is an increased risk of malignancy in older women. Ovarian tumours are subdivided into five main categories according to the World Health Organization's classification system (Table 80.4).

Table 80.4 Classification of ovarian tumours.

Epithelial tumours	Represent about 75% of all ovarian tumours and 90–95% of ovarian malignancies
Sex cord–stromal tumours	Represent about 5–10% of all ovarian neoplasms
Germ cell tumours	Represent about 15–20% of all ovarian neoplasms
Metastatic tumours	Represent about 5% of ovarian malignancies; usually arise from breast, colon, endometrium, stomach and cervical cancers
Other	A small number of other types of neoplasms, which develop from ovarian soft tissue or non-neoplastic processes

The most common solid tumours in young women are cystic teratomas (known more commonly as dermoid cysts), which typically contain a variety of tissues including hair, teeth and bone. Benign ovarian tumours are often asymptomatic and may present coincidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling and pressure effects. The pain may be the result of torsion or bleeding inside the cysts. Management will depend, to some extent, on the age of the woman and the characteristics of the cyst. In older women, a conservative approach is reasonable only if the risks of malignancy are low (see Ovarian cancer). In younger women (<35 years), the cyst can be followed by serial ultrasound scanning as many will regress – haemorrhagic corpus luteal cysts, for example, will often shrink after three to four months' treatment with a COC. If there is uncontrollable pain, haemodynamic collapse or a suspicion of torsion, or the cyst does not regress, then laparoscopic ovarian cystectomy with conservation of ovarian tissue is the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (Figure 80.14) (Summary box 80.6).

Summary box 80.6

Management of benign ovarian cysts

- Masses are usually detected incidentally but may be suggested by symptoms and signs
- A pregnancy test is done to exclude ectopic pregnancy
- Transvaginal ultrasonography can usually confirm the diagnosis. If results are indeterminate, magnetic resonance imaging or computed tomography scanning may help. Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multilocular appearance, irregular shape) require removal
- Tumour markers may help in the diagnosis of specific tumours
- In women of reproductive age, simple, thin-walled cystic adnexal masses of 5–8 cm (usually follicular) without characteristics of cancer do not require further investigation unless they persist for more than three menstrual cycles
- Many ovarian cysts resolve without treatment; serial ultrasonography is carried out to document resolution. Cyst removal (ovarian cystectomy) via laparoscopy or laparotomy may be necessary for cysts ≥ 8 cm, cysts that persist for more than three menstrual cycles and haemorrhagic corpus luteum cysts with signs of peritonitis
- Cystic teratomas require removal via cystectomy if possible. Oophorectomy is carried out for fibromas, cystadenomas, cystic teratomas >10 cm and cysts that cannot be surgically removed from the ovary

Ovarian cancer

Ovarian cancer is the sixth most common malignancy among women worldwide and the leading gynaecological cause of death in the developing world. In the UK, over 6000 women die annually from ovarian cancer. Over 90 per cent of cancers arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority are sporadic rather than inherited. The peak incidence is in the age range of 60–70 years. The overall five-year survival rate is less than 50 per

Figure 80.14 Ovarian cystectomy.

cent because approximately two-thirds of women present with advanced disease. The usual presenting symptoms are:

- abdominal distension and/or pain;
- weight gain and increased girth (ascites);
- urinary obstruction.

However, over half of all women present initially to a specialty other than gynaecology, with often vague symptoms caused by metastatic disease, e.g. shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with recent onset of persistent, non-specific, abdominal symptoms (including those whose abdomen and pelvis appears normal on clinical examination).

Ultrasound is the first-line investigation if an ovarian mass is suspected on clinical grounds. The features suggestive of malignancy on ultrasound include the presence of:

- cyst complexity (number of locules, wall structure, thickness of septae, fluid echogenicity);
- solid papillary projections into the cyst;
- bilateral lesions;
- ascites;
- intra-abdominal metastases.

The level of cancer antigen 125 (CA-125; a glycoprotein expressed on tissue derived from coelomic and Müllerian epithelia) in serum is measured; the normal cut-off value is 35 U/mL. Elevated levels are found in 50 per cent of patients with stage I disease and >90 per cent of those with advanced disease. However, CA-125 levels are also elevated in other cancers, e.g. pancreas, breast, lung and colon. Levels may even be raised during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. The value of combining the ultrasound and CA-125 measurements is such that a postmenopausal woman with a simple, unilateral, unilocular cyst of <5 cm in diameter and a normal serum CA-125 level should be managed conservatively (Summary box 80.7).

Summary box 80.7

Basic tests on suspicion of ovarian malignancy

- Ultrasonography: findings that suggest cancer include a solid component, surface excrescences, size >6 cm, irregular shape and low vascular resistance on transvaginal Doppler flow studies
- A pelvic mass plus ascites usually indicates ovarian cancer but sometimes indicates Meigs' syndrome (a benign fibroma with ascites and right hydrothorax)
- Computed tomography scan or magnetic resonance imaging is usually carried out before surgery to determine the extent of the cancer
- Tumour markers, including the β -subunit of human chorionic gonadotropin (β -hCG), lactate dehydrogenase, α -fetoprotein, inhibin and CA-125, are also measured
- CA-125 is elevated in 80 per cent of advanced epithelial ovarian cancers, but may be mildly elevated in endometriosis, pelvic inflammatory disease, pregnancy, fibroids, peritoneal inflammation and non-ovarian peritoneal cancer.

Unfortunately, there are still no effective screening methods for ovarian cancer for the general population. Hence, the preliminary results of the UK Collaborative Trial of Ovarian Cancer Screening are of great interest. The study has recruited over 200 000 women, aged 50–74 years, who have been randomised to a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by transvaginal ultrasound as a second-line test or transvaginal ultrasound alone. The two screening procedures were similar in terms of sensitivity for all primary ovarian and Fallopian tube cancers, but specificity was higher with combined screening (99.8 versus 98.2 per cent; $p < 0.001$).

There is also no consensus regarding how women who are at high risk because of a family history should be screened, i.e. those with a first-degree relative affected by cancer within a family that meet one of the following criteria:

- Two or more individuals with ovarian cancer, who are first-degree relatives of each other.
- One individual with ovarian cancer at any age and one with breast cancer diagnosed at <50 years, who are first-degree relatives of each other (or second-degree relatives if the transmission is paternal).
- One relative with ovarian cancer at any age and two with breast cancer diagnosed at <60 years, who are connected by first-degree relationships (or second-degree relationships if the transmission is paternal).
- Known carrier of relevant cancer gene mutations (e.g. BRCA1 or BRCA2).
- Untested first-degree relative of a predisposing gene carrier.
- Three or more family members with colon cancer or two with colon cancer and one with stomach, ovarian, endometrial, urinary tract or small bowel cancer in two generations. One of these cancers must be diagnosed at <50 years of age (Lynch syndrome).
- An individual with both breast and ovarian cancer.

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany, described the paramesonephric duct in 1825.

Joe Vincent Meigs, 1892–1964, gynaecological surgeon, Massachusetts General Hospital, Boston, MA, USA.

A first-degree relationship is that between parent and child.

A second-degree relationship is that between siblings (i.e. via the parent), and between a grandparent and a grandchild.

Table 80.5 Staging of ovarian cancer.

Stage I	Growth limited to the ovaries
Stage II	Growth involving one or both ovaries with pelvic extension
Stage III	Tumour involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals stage III. Tumour is limited to the true pelvis, but with histologically proven extension to the small bowel or omentum
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to classify a case as stage IV. Parenchymal liver metastasis equals stage IV

Some genetic mutations are known to predispose women to ovarian cancer, e.g. *BRCA1* and *BRCA2* and the mismatch repair genes associated with HNPCC (Lynch syndrome) families. *BRCA1* mutations confer a 30 per cent lifetime risk of ovarian cancer up to the age of 60 years; the figure for *BRCA2* mutations is 27 per cent up to the age of 70 years. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12 per cent, in addition to the increased risk of endometrial cancer (see above under Vaginal bleeding in the non-pregnant state). Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered prophylactic oophorectomy, especially as they may also be at increased risk of breast cancer and there is some evidence to suggest that oophorectomy reduces breast cancer risk in these women. Unfortunately, there is no proven role for screening in women at high risk.

Staging (Table 80.5) is performed at laparotomy via a midline incision if disease is suspected preoperatively by:

- Careful evaluation of all peritoneal surfaces.
- Four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis.
- Infracolic omentectomy.
- Selected lymphadenectomy of the pelvic and para-aortic lymph nodes.
- Biopsy and/or resection of any suspicious lesions, masses and any adhesions.
- Random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemidiaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls.
- Total abdominal hysterectomy and bilateral salpingo-oophorectomy.
- Appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from any suspicious area.

Surgery is the mainstay of treatment for ovarian cancer. The staging laparotomy and histological findings provide accurate information about prognosis and postoperative therapy. The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer need bowel resected during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests unilateral oophorectomy to conserve her fertility.

Stage I/grade 1 epithelial adenocarcinoma requires no post-operative therapy. Stage I/grade 2 or 3 cancers and stage II cancers require six courses of chemotherapy (typically, paclitaxel and carboplatin). Stage III or IV cancer requires six courses of similar chemotherapy. Intraperitoneal chemotherapy or high-dose chemotherapy with bone marrow transplantation is under study. Radiation therapy is used infrequently. Even if chemotherapy results in a complete clinical response (i.e. normal physical examination, normal serum CA-125 and negative CT scan of the abdomen and pelvis), about 50 per cent of such patients with stage III or IV cancer will have residual tumour. Of patients with persistent elevation of CA-125, 90–95 per cent have residual tumour.

Ovarian stimulation with oocyte or embryo freezing has been reported in patients with low-grade tumours who wish to preserve fertility, but the effect of this on the underlying disease is as yet unknown and it must therefore be carried out with caution.

Transplantation

81 Transplantation

1407

CHAPTER 81

Transplantation

LEARNING OBJECTIVES

- To appreciate the immunological basis of allograft rejection
- To know the principles of immunosuppressive therapy
- To be aware of the side effects of non-specific immunosuppression
- To be familiar with the major issues concerning organ donation
- To appreciate the main indications for organ transplantation
- To know the surgical principles of organ implantation
- To be able to give an account of the causes of graft dysfunction
- To know the likely outcomes after transplantation
- To be aware of potential future developments in transplantation

HISTORICAL PERSPECTIVE

Since early times, the idea of tissue and organ transplantation has captured the imagination of successive generations and, over the centuries, numerous fanciful descriptions of successful transplants have been recorded. One of the most widely cited early examples is that of the Christian Arab Saints Cosmas and Damian. Around ad 300, they were reputed to have successfully replaced the diseased leg of a patient with that from another man who had died several days earlier (Figure 81.1).

The modern era of transplantation began in the 1950s (Table 81.1) and relied on surgical techniques for anastomosing blood vessels that had been developed at the beginning of the twentieth century by Mathieu Jaboulay and Alexis Carrel. The first successful kidney transplant was a living-donor transplant performed between identical twins in 1954 at the Brigham Hospital in Boston by Joseph Murray and colleagues. This, and other kidney transplants between identical twins, demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppressive therapy was available (Figure 81.2). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Calne showed that

Alexis Carrel, 1873–1944, was a surgeon from Lyons in France, who worked at the Rockefeller Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'In recognition of his works on vascular suture and the transplantation of blood vessels and organs'.

Joseph E Murray, born 1919, Professor Emeritus of Plastic Surgery, The Harvard University Medical School, Boston, MA, USA. He shared the 1990 Nobel Prize for Physiology or Medicine with E Donnall Thomas for his work on organ and cell transplantation

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.

Robert S Schwartz, Professor of Medicine, The Tufts University School of Medicine, Boston, MA, USA.

William Dameshek, 1900–1969, an American physician and haematologist.

Figure 81.1 Depiction of Saints Cosmas and Damian performing a miraculous transplantation of the leg. Oil painting attributed to the Master of Los Balbases (Wellcome Institute Library, London).

azathioprine, a derivative of 6-mercaptopurine, prevented rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with moderate success in the clinic to prevent graft rejection after

Table 81.1 Milestones in organ transplantation.

1954	Joe Murray performed successful kidney transplants between identical twins (Boston, MA, USA)
1962	Roy Calne demonstrated the efficacy of azathioprine in preventing rejection of kidney allografts (Boston, MA, USA)
1963	Tom Starzl performed the first human liver transplant (Denver, CO, USA)
1966	Tom Starzl and colleagues used antilymphocyte globulin immunosuppression (Denver, CO, USA)
1966	Richard Lillehei and William Kelly performed first human whole organ pancreas transplant (along with a kidney transplant) (Minneapolis, MN, USA)
1967	Christiaan Barnard performed the first human heart transplant (Cape Town, South Africa)
1968	Fritz Derom performed the first human lung transplant (Ghent, Belgium)
1969	Geoff Collins developed Collins solution – a new kidney preservation solution
1974	David Sutherland and John Najarin performed the first human pancreatic islet transplant (Minneapolis, MN, USA)
1978	Roy Calne introduced ciclosporin into clinical practice (Cambridge, UK)
1981	Bruce Reitz and Norman Shumway performed the first successful human heart-lung transplant (Stanford, CA, USA)
1987	Fokert Belzer and colleagues developed University of Wisconsin (UW) solution – a new liver and pancreas preservation solution (Wisconsin, USA)
1989	Tom Starzl demonstrated clinical efficacy of FK506 (tacrolimus) (Pittsburgh, PA, USA)
1995	Lloyd Ratner and colleagues first described laparoscopic living-donor nephrectomy (Johns Hopkins University, Baltimore, MD, USA)

kidney transplantation. These chemical agents were sometimes supplemented with a polyclonal antilymphocyte antibody.

The ciclosporin era began in the late 1970s following its discovery by Borel at the Sandoz laboratories in Basle and the demonstration, by Calne in Cambridge, UK, of its potent immunosuppressive properties in clinical transplantation. The introduction of ciclosporin was a major advance and ciclosporin (usually given together with azathioprine and steroids) not only improved the results of renal transplantation, but also allowed transplantation of the heart and liver to be undertaken with acceptable results. Organ transplantation is now well established as an effective treatment for selected patients with end-stage organ failure. Kidney, liver, pancreas, heart and lung transplantation are all routine procedures with good outcome, and transplantation of the small intestine is becoming more widely practised. Transplant activity is limited only by the shortage of donor organs.

Definitions of common terms in the area of organ transplantation are given in Summary box 81.1.

Summary box 81.1

Definitions

- **Allograft:** an organ or tissue transplanted from one individual to another
- **Alloantigen:** transplant antigen
- **Alloantibody:** transplant antibodies
- **HLA:** human leukocyte antigen, the main trigger to graft rejection
- **Xenograft:** a graft performed between different species
- **Orthotopic graft:** a graft placed in its normal anatomical site
- **Heterotopic graft:** a graft placed in a site different from that where the organ is normally located

GRAFT REJECTION

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a non-specific inflammatory response and subsequent studies demonstrated that T lymphocytes play an essential role in mediating rejection.

Allografts trigger a graft rejection response because of allelic differences at polymorphic genes that give rise to histocompatibility antigens (transplant antigens) of which ABO blood group antigens and human leukocyte antigens (HLA) are the most important.

ABO blood group antigens

The ABO blood group antigens are expressed not only by red blood cells, but by most other cell types as well. It is vitally

Figure 81.2 One of the early Boston recipients of a kidney transplant from an identical twin, shown here with her twin sister and their children.

Sir Roy York Calne, Emeritus Professor of Surgery, The University of Cambridge, Cambridge, UK. In 1968 he performed Europe's first liver transplant. He was associated with the world's first liver, heart and lung transplant in 1987. He was elected Fellow of the Royal Society in 1974. He is an accomplished painter who has painted many of his transplant patients and has had exhibitions worldwide.

Sir Peter Brian Medawar, 1915–1987, a zoologist and immunologist and who was Director of the National Institute of Medical Research, London, UK. He shared the 1968 Nobel Prize for Physiology or Medicine with Sir Frank Macfarlane Burnet, for his research into immunological tolerance.

important, for all types of organ allograft, to ensure that recipients do not unintentionally receive a graft that is ABO blood group compatible otherwise naturally occurring anti-A or anti-B antibodies will likely cause hyperacute graft rejection.

Permissible transplants are:

- group O donor to group O, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of rhesus antigen compatibility in organ transplantation.

HLA antigens

Allograft rejection (in blood group-compatible grafts) is directed predominantly against HLA – a group of highly polymorphic cell-surface molecules. HLA are strong transplant antigens by virtue of their special physiological role as antigen recognition units for display of antigens from foreign pathogens for recognition by T lymphocytes. It was through their role in stimulating graft rejection responses that their existence was first demonstrated by Dausset in 1958, hence their description as major histocompatibility antigens (Summary box 81.2).

Summary box 81.2

HLA antigens

- Are the most common cause of graft rejection
- Their physiological function is to act as antigen recognition units
- Are highly polymorphic (amino acid sequence differs widely between individuals)
- HLA-A, -B (class I) and -DR (class II) are most important in organ transplantation

Jean Dausset, born 1916, a French immunologist who was Professor of Experimental Medicine at The College of France, Paris, France. He shared the 1980 Nobel Prize for Physiology or Medicine with George Snell and Baruj Benacerraf for his discovery of the HLA antigens.

Table 81.2 HLA class I and HLA class II molecules.

	Class I	Class II
HLA loci	HLA-A, -B and -C	HLA-DR, -DP and -DQ
Structure	Heavy chain and β_2 -microglobulin	α - and β -chain
Distribution	All nucleated cells	B cells, dendritic cells, macrophages

There are two types of HLA molecule: HLA class I and HLA class II (Table 81.2). They are broadly similar in structure (Figure 81.3) but have different cell expression profiles. HLA class I antigens are present on all nucleated cells, whereas HLA class II antigens have a more restricted distribution and are expressed most strongly on antigen-presenting cells, such as dendritic cells, macrophages and B lymphocytes. T cells recognize HLA molecules via their T-cell receptor but full T-cell activation also requires the delivery of an additional or second signal delivered by the interaction of costimulatory molecules on the surface of the antigen-presenting cell and T cell (Figure 81.4).

Effector mechanisms of rejection

HLA antigens expressed by graft cells activate T cells and stimulate them to proliferate in response to interleukin-2 (IL-2) and other T-cell growth factors. Activated CD4 T cells, through release of cytokines, play a central role in orchestrating the various effector mechanisms responsible for graft rejection (Figure 81.5). The cellular effectors of graft rejection include cytotoxic CD8 T cells, that recognise donor HLA class I antigens expressed by the graft and cause target cell death by releasing lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T cells, which recognise donor HLA class II antigens, mediate direct target cell damage and are also able, by releasing proinflammatory cytokines such as interferon- γ , to recruit and activate macrophages that act as non-specific effector cells. Finally, CD4 T cells provide essential T-cell help for B lymphocytes that differentiate into plasma cells and produce

Figure 81.3 The three-dimensional structure of the extracellular domains of human leukocyte antigen (HLA) class I and class II. The α_1 and α_2 domains of class I and the α_1 and β_1 domains of class II form a cleft that is floored by a β -pleated sheet and walled by two α -helices. The cleft binds an antigenic peptide and displays it on the cell surface for recognition by a T lymphocyte. (Redrawn with permission from Stern and Wiley (1994) Structure 2: 245–52.)

Figure 81.4 Molecular events involved in T-cell activation by an antigen-presenting cell. T-cell activation requires the delivery of two distinct signals to the T cell. The first signal is delivered by ligation of the TCR/CD3 complex with human leukocyte antigen (HLA)/peptide complex. The second signal is delivered following the interaction between pairs of costimulatory molecules such as CD28 with CD80/86 and CD154 with CD40.

alloantibodies that bind to graft antigen and induce target cell injury directly or through antibody-dependent, cell-mediated cytotoxicity.

Types of allograft rejection

Allograft rejection can be divided into three distinct types (Summary box 81.3):

- 1 hyperacute rejection (occurs immediately);
- 2 acute rejection (usually occurs in the first six months);
- 3 chronic rejection (occurs months and years after transplantation).

Allograft rejection manifests itself as functional failure of the transplant and is confirmed by histological examination. Biopsy material is obtained from renal and pancreas grafts by needle biopsy, and from hepatic grafts by percutaneous or transjugular liver biopsy. Cardiac grafts are biopsied by transjugular endomyocardial biopsy and lung grafts by transbronchial biopsy. After small intestinal transplantation, mucosal biopsies are obtained from the graft stoma or more proximally by endoscopy.

Summary box 81.3

Types of graft rejection

- Hyperacute rejection
 - Immediate graft destruction due to ABO or preformed anti-HLA antibodies
 - Characterised by intravascular thrombosis and interstitial haemorrhage
- Acute rejection
 - Usually occurs during first six months
 - T cell dependent
 - May be cell-mediated, antibody-mediated or both
 - Usually reversible
- Chronic rejection
 - Occurs after first six months
 - Most common cause of graft failure
 - Antibodies play an important role
 - Non-immune factors contribute to pathogenesis
 - Characterised by myointimal proliferation in graft arteries leading to ischaemia and fibrosis

A standardised histological grading system, termed the Banff classification (named after the Canadian town where the initial scientific workshop was held), defines the presence and severity of allograft rejection after organ transplantation.

Hyperacute rejection

This is due to the presence in the recipient of preformed antibodies against HLA class I antigens expressed by the donor. These arise from a previous blood transfusion, a failed transplant and pregnancy. This type of rejection also occurs if an ABO blood group-incompatible organ graft is performed inadvertently. After revascularisation of the graft, antibodies bind immediately to the vasculature, activate the complement system and cause extensive intravascular thrombosis, interstitial haemorrhage and graft destruction within minutes and hours. Kidney transplants are particularly vulnerable to hyperacute graft rejection, whereas heart and liver transplants are relatively resistant. It is not clear why the liver is resistant to hyperacute rejection. One factor may be that it is less susceptible to ischaemia than the kidney by virtue of its dual blood supply: 60 per cent of

Figure 81.5 The central role of the CD4 T cell in orchestrating the various effector mechanisms responsible for allograft rejection. APC, antigen-presenting cell; DTH, delayed-type hypersensitivity; IFN- γ , interferon-gamma; IL, interleukin; M Φ , macrophage; MHC, major histocompatibility complex; NK, natural killer; Tc, T cytotoxic cell; T_{cp}, T cytotoxic precursor cell; TCR, T-cell receptor.

the hepatic blood supply is derived from the portal vein and 40 per cent from the hepatic artery.

Hyperacute rejection can be avoided by ensuring ABO blood group compatibility and by performing a cross-match test on recipient serum to ensure that there are no clinically relevant antibodies directed against HLA antigens expressed by a prospective kidney donor.

Acute rejection

This usually occurs during the first six months of transplantation but may occur later. It is mediated predominantly by T lymphocytes, but alloantibodies may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (Figure 81.6). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T cells, B cells, NK cells and activated macrophages. Antibody-mediated damage may also be present as evidenced by the deposition of the complement component C4d within the graft microvasculature (Figure 81.7). All types of organ allograft are susceptible to acute rejection, and although relatively common (typically occurring in around 20–30 per cent of grafts), most episodes of acute rejection can be reversed by additional immunosuppressive therapy.

Chronic rejection

This usually occurs after the first six months. All types of transplant are susceptible to chronic rejection, and it is the major cause of allograft failure. Interestingly, the liver is more resistant than other organs to the destructive effects of chronic rejection. The pathophysiology of chronic rejection is not well understood. The underlying mechanisms are immunological, and alloantibodies are thought to be a major cause although cellular effector mechanisms may also contribute. Alloantigen-independent factors also contribute. The risk factors for chronic rejection of a kidney transplant are:

- previous episodes of acute rejection;
- poor HLA match;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (including poor compliance).

Figure 81.6 Severe acute renal allograft rejection with a heavy mononuclear cell infiltrate and intimal arteritis.

Figure 81.7 Acute antibody-mediated renal allograft rejection. There is widespread staining for the complement component C4d within the peritubular capillaries (arrows) that indicates alloantibody binding to the graft vasculature.

The single most important risk factor for chronic rejection after kidney transplantation is acute rejection (with vascular inflammation) and recurrent episodes of acute rejection. Because non-immune factors often contribute significantly to the long-term failure of a kidney transplant, the term ‘chronic allograft nephropathy’ is sometimes used.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myointimal proliferation in arteries, which results in ischaemia and fibrosis (Figure 81.8). In addition to vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney: glomerular sclerosis and tubular atrophy;
- pancreas: acinar loss and islet destruction;
- heart: accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver: vanishing bile duct syndrome;
- lungs: obliterative bronchiolitis.

Figure 81.8 Chronic renal allograft rejection. The arteriole shows severe myointimal proliferation and luminal narrowing, resulting in ischaemic fibrosis.

Chronic rejection causes functional deterioration in the graft, resulting after months or years in complete graft failure. Unfortunately, currently available immunosuppressive therapy has had little effect in preventing chronic rejection.

Graft-versus-host disease

Although the main immunological problem after transplantation is graft rejection, the reciprocal problem of graft-versus-host reaction is occasionally seen following certain types of organ transplantation. Some donor organs (particularly liver and small bowel) contain large numbers of lymphocytes, and these may react against HLA antigens expressed by recipient tissues, leading to graft-versus-host disease (GVHD). GVHD frequently involves the skin, causing a characteristic rash on the palms and soles. It may also involve the liver (after small bowel transplantation) and the gastrointestinal tract (after liver transplantation). GVHD is a serious and sometimes fatal complication.

HLA MATCHING

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (Figure 81.9). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP and -DQ. Expression of MHC genes is co-dominant, i.e. the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between 6 and 12 different HLA antigens, depending on the degree of homozygosity (shared genes) at individual loci.

The HLA haplotype inherited from each parent is usually inherited as a complete haplotype, according to simple Mendelian genetics (Figure 81.10). In deceased donor renal transplantation (but not other types of organ transplantation), attempts are usually made to match the donor and recipient for as many of the relevant HLA antigens as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allograft

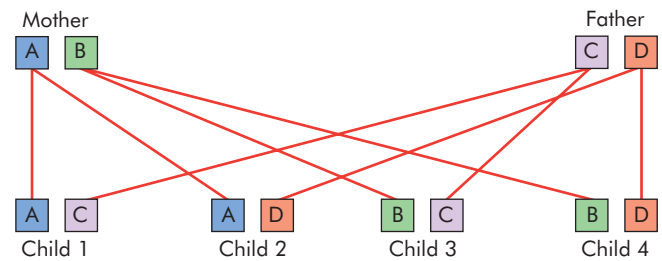

Figure 81.10 Human leukocyte antigen (HLA) inheritance. Children acquire one HLA haplotype (depicted as A–D) from each parent. As shown, child 1 shares one HLA haplotype (haploidentical) with child 2 and child 3, but does not share either haplotype with child 4. The chances that two siblings will share the same parental haplotypes, or that they will share neither HLA haplotype, is one in four. The chance that they will share one HLA haplotype is one in two.

that subsequently fails is less likely to cause sensitisation to the HLA antigens that it expresses. It is particularly important in children and young adults to avoid, where possible, grafts that are mismatched for common HLA antigens because, if retransplantation is required subsequently, it may be difficult to find an organ donor who does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important antigens to take into account when matching donor and recipient in an attempt to reduce the risk of graft rejection (Figure 81.11).

HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and also are troubled less by rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A '000 mismatch' is a 'full-house' or complete match, whereas a '012 mismatch' is matched at

Approximate number of alleles defined by molecular typing

Figure 81.9 The human leukocyte antigen (HLA) system on the short arm of chromosome 6.

Gregor Johann Mendel, 1822–1884, an Austrian monk and naturalist who became Abbot of the Augustinian Monastery at Brunn, the Czech Republic and discovered the laws of inheritance by studying the edible pea. In 1865 he described 'dominant' and 'recessive' traits in hybrids. His work passed unnoticed for 35 years.

HLA-A+B+DR mismatches
Deceased donor, first kidney transplants 1985–2009

Figure 81.11 Beneficial effect of human leukocyte antigen (HLA) matching (HLA-A, -B and -DR) on first deceased donor renal allograft survival (courtesy of Gerhard Opelz, Collaborative Transplant Study, CTC-K21101-0211). MM, antigen mismatch.

HLA-A loci, has one mismatched HLA-B antigen and is mismatched for both DR antigens. Deceased donor kidneys are allocated in some countries, including the UK, by a points system that optimises HLA matching but also takes into account other factors, such as time on the waiting list, sensitisation to HLA antigens and the age relationship between the donor and recipient. Allocation of organs for transplantation must also take into account the relative size of donor and recipient. This is not an issue in renal transplantation, and adult kidneys can be readily used for paediatric recipients (and vice versa). However, in the case of heart, lung, liver and small bowel transplantation, it is important to consider size compatibility between the donor and recipient. In the case of liver transplants, HLA matching does not confer an advantage and, although it is beneficial in cardiac transplantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

THE TISSUE-TYPING LABORATORY

Successful organ transplantation requires a close-working relationship between the tissue-typing laboratory and the clinical transplant team. The tissue-typing laboratory carries out three key tasks. First, they determine the HLA type ('tissue type') of all potential organ transplant recipients and organ donors. This is achieved by applying polymerase chain reaction-based DNA-typing techniques to samples of peripheral blood. Second, they perform a cross-match test to exclude the presence in a recipient of clinically significant circulating antibodies to HLA antigens expressed by a potential organ donor that would result in rapid or hyperacute graft rejection. This involves incubating recipient sera with donor lymphocytes prepared from either blood or lymphoid tissue. The presence of antidonor antibodies is detected in a conventional cytotoxic cross-match assay by adding rabbit complement along with indicator dyes and visualising target cell death. More often now a flow cytometric cross-match is performed as well as, or instead of, a cytotoxic cross-match. Third, the tissue-typing laboratory determines the HLA specificity of circulating anti-HLA antibodies in recipients before and after organ transplantation to guide organ allocation and immunosuppressive therapy. This task has been revolutionised by the availability of solid phase assays, particularly Luminex technology, where patient sera are incubated with a panel of latex beads coated with purified HLA molecules and antibody binding detected by flow cytometric analysis.

Patients on the renal transplant waiting list should be screened for the development of HLA antibodies on a regular

basis and especially after potential priming to HLA antigens by blood transfusion.

If, when considering renal transplantation the cross-match test is strongly positive, transplantation should not proceed, otherwise hyperacute rejection is likely. Antibodies directed against HLA class II antigens, unlike those to HLA class I, do not usually cause hyperacute rejection but are associated with acute rejection and a poor clinical outcome. Patients awaiting heart transplantation are also screened for the presence of HLA antibodies and those with preformed antibodies are subjected to a prospective cross-match test. Although heart allografts rarely undergo hyperacute rejection, transplantation in the presence of a positive cross-match is associated with graft loss from accelerated acute rejection. Even in the presence of a strongly positive cross-match test, liver transplants rarely undergo hyperacute rejection, although long-term survival is reduced.

IMMUNOSUPPRESSIVE THERAPY

A range of different agents are available that act at different sites during T-cell activation to prevent rejection (Table 81.3 and Figure 81.12). They can be classified according to their principal mode of action.

Table 81.3 Immunosuppressive agents.

Agent	Principal mode of action
Corticosteroids	Widespread anti-inflammatory effects
Azathioprine	Prevents lymphocyte proliferation
Mycophenolic acid preparations	Prevents lymphocyte proliferation
Calcineurin inhibitors (cyclosporin/tacrolimus)	Blocks IL-2 gene transcription
mTOR inhibitors	Blocks IL-2 receptor signal transduction
ALG	Depletion and blockade of lymphocytes
Anti-CD25 mAb	Targets activated T cells
Anti-CD52 mAb	Depletion of lymphocytes
Anti-CD20	Depletion of B lymphocytes
CTLA-4Ig	Blocks T-cell costimulation

IL-2, interleukin-2.

Figure 81.12 Site of action of immunosuppressive agents on T cell. ATG, antithymocyte globulin; MPA, mycophenolic acid derivatives; mTOR, mammalian target of rapamycin.

Calcineurin inhibitors (ciclosporin and tacrolimus)

Ciclosporin and tacrolimus are the mainstay of most modern immunosuppressive protocols for organ transplantation. Although structurally distinct, they exert their principal immunosuppressive effect through the same intracellular pathway. Each of the two agents binds within the T cell to a cytoplasmic protein or immunophilin (ciclosporin binds to cyclophilin and tacrolimus to FK-binding protein). The resulting immunophilin-drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, ciclosporin and tacrolimus exert a potent immunosuppressive effect. The two agents share a number of side effects, the most notable of which is nephrotoxicity (Table 81.4). Ciclosporin sometimes causes cosmetic side effects (hirsutism and gingival hypertrophy) that may be distressing, particularly in younger female recipients. The calcineurin inhibitors (CNIs) have a relatively small therapeutic window. Their immunosuppressive action, as well as their side effects, is dependent on their blood concentration, and monitoring of whole-blood drug levels is an important guide to optimal therapy. Ciclosporin and tacrolimus are broadly equivalent in terms of long-term graft survival but increasing evidence suggests tacrolimus is more effective in reducing acute rejection. The choice between the two agents depends on the preference of the transplant unit and on individual patient tolerance to the different side effects of the two agents.

Table 81.4 Agent-specific side effects of immunosuppressive agents used in organ transplantation (all immunosuppressive agents increase the risk of infection).

Agent	Side effects (not comprehensive)
Corticosteroids	Hypertension, dyslipidaemia, diabetes, osteoporosis, avascular necrosis, Cushingoid appearance
Azathioprine	Leukopenia, thrombocytopenia, hepatotoxicity, gastrointestinal symptoms
Mycophenolic acid derivatives	Leukopenia, thrombocytopenia, gastrointestinal symptoms
Ciclosporin	Nephrotoxicity, hypertension, dyslipidaemia, hirsutism, gingival hyperplasia
Tacrolimus	Nephrotoxicity, hypertension, dyslipidaemia, neurotoxicity, diabetes
mTOR inhibitors	Thrombocytopenia, dyslipidaemia, pneumonitis, impaired wound healing
ALG	Infusion reactions, leukopenia and thrombocytopenia
Anti-CD25	Uncommon
CTLA-4Ig	? Increased risk of PTLD
Anti-CD52	Infusion reaction and autoimmune disease
Anti-CD20	Infusion reactions and pulmonary toxicity

ALG, antilymphocyte globulin; mTOR, mammalian target of rapamycin; PTLD, post-transplant lymphoproliferative disease.

Antiproliferative agents (azathioprine and mycophenolate)

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion is an integral part of the immune response to an allograft. The antiproliferative agents available for immunoprophylaxis are azathioprine and mycophenolic acid preparations (mycophenolate mofetil (MMF) and mycophenolic acid sodium (MPAS)). Azathioprine is converted in the liver to its active metabolite, 6-mercaptopurine, which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolic acid (MPA) preparations are more expensive than azathioprine but have largely replaced it as the agents of choice. After ingestion, MMF is converted to its active metabolite MPA. It inhibits the enzyme inosine monophosphate dehydrogenase, which is the rate-limiting enzyme in the *de novo* pathway of purine nucleotide synthesis. Because lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired. The main side effects of azathioprine and MPA are bone marrow suppression and gastrointestinal symptoms.

Steroids

Steroids are an important component of many immunosuppressive regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. Because of their numerous and well-known side effects, some centres attempt to gradually withdraw steroids from patients who have stable graft function after transplantation, but this sometimes precipitates a rejection episode and necessitates recommencement of steroids.

Antibody therapies

Monoclonal antibodies directed against the IL-2 receptor on T lymphocytes (CD25) are commonly given at the time of transplantation to temporarily augment the effects of calcineurin blockade during the early post-transplant period. Their effect lasts for a few weeks only and they lack any significant agent-specific side effects. Polyclonal antibody (antithymocyte globulin (ATG)) and monoclonal antibody preparations (alemtuzumab (anti-CD52 expressed on T cells and dendritic cells)) are also quite widely used as more potent and alternative induction agents. They cause a temporary depletion of circulating lymphocytes that reduces rejection but may lead to an increase in infection and malignancy. In addition to their use as induction agents, antibody preparations may be used to treat acute rejection episodes that fail to respond to steroid therapy.

The monoclonal anti-CD20 antibody (rituximab) depletes B lymphocytes and is widely used as a component of desensitisation protocols to enable ABO and HLA antibody-incompatible renal transplantation. It may also be helpful for the treatment of antibody-mediated acute rejection although its efficacy here is limited because it does not deplete antibody-producing plasma cells.

Mammalian target of rapamycin inhibitors (sirolimus and everolimus)

Sirolimus and its structural analogue everolimus are, like tacrolimus, macrolides that bind within T lymphocytes to FK-binding protein. However, their mode of action is completely different to that of both ciclosporin and tacrolimus.

They act by inhibiting an intracellular kinase called mammalian target of rapamycin (mTOR) and interfere with intracellular signalling from the IL-2 receptor, arresting T-cell division in the G1 phase. In contrast to CNIs they are not nephrotoxic. However, their side effect profile includes lymphocele formation, impaired wound healing, an adverse effect on the blood lipid profile, thrombocytopenia and very occasionally pneumonitis. mTOR inhibitors may have antitumour activity and the potential value of this effect in transplant patients is under investigation. Although the negative effect on wound healing and lymphocele formation limits the immediate use of mTOR inhibitors after transplantation, switching from CNIs to mTOR inhibitors is being used increasingly as a strategy to minimise CNI-induced nephrotoxicity.

T-cell costimulatory blockers

CTLA-4Ig (belatacept, LEA29Y) is a fusion protein comprising the extracellular domain of CTLA-4 fused to human IgFc. It binds to the costimulatory ligands CD80 and CD86 expressed on antigen-presenting cells and as a result prevents them from delivering the costimulatory signals to the T cells that are required for full T-cell activation. It has recently been shown in renal transplantation to provide an effective alternative to CNIs when given by regular i.v. injection, thereby avoiding the metabolic, cardiovascular and nephrotoxic effects of CNIs. Although its future looks very promising, a potential concern is that it may be associated with an increased risk of post-transplant lymphoproliferative disease (PTLD).

Immunosuppressive regimens

When selecting an immunosuppressive regimen, the challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection without exposing the recipient to excessive risk from infection and malignancy as a result of non-specific immunosuppression (Summary box 81.4). Immunosuppressive therapy is started at the time of transplantation and is continued indefinitely (as maintenance therapy), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest. Immunosuppressive protocols vary, but all use a combination of immunosuppressive agents acting at different points in the pathway of lymphocyte activation. Most currently include a CNI (ciclosporin or tacrolimus) as the main agent and often this is supplemented with anti-CD25 monoclonal antibody induction therapy. CNIs are usually combined with an antiproliferative agent (most often MMF) and steroids, so-called triple therapy. Less often, a CNI is used with an anti-

proliferative agent alone or with steroids alone (dual therapy). When there is particular concern about acute rejection, polyclonal or monoclonal antibody preparations are administered followed by a CNI, an antiproliferative agent and steroids.

The principles of immunoprophylaxis are similar for all types of organ transplantation. Interestingly, liver grafts seem to be less susceptible to rejection for reasons that are still unclear. The mTOR inhibitors have been shown to be effective immunosuppressive agents for preventing acute rejection following kidney transplantation and they provide a non-nephrotoxic alternative to CNIs for maintenance therapy. They have a similar safety profile to CNIs in terms of post-transplant infection but some of their agent-specific side effects are of potential concern and their clinical niche is still to be fully determined. Similarly, the potential role that CTLA-4Ig will find as an alternative to CNIs remains to be seen.

Acute rejection occurs in up to around 30 per cent of transplant recipients but usually responds to a short course of high-dose steroid therapy. If the response to steroids is inadequate or if acute rejection recurs, acute rejection can often be treated successfully by recourse to antilymphocyte globulin (ALG) therapy.

COMPLICATIONS OF IMMUNOSUPPRESSION

As well as the agent-specific side effects already mentioned, the immunosuppressive agents used in organ transplantation cause non-specific immunosuppression and increase the risk of both infection and malignancy (Summary box 81.5).

Summary box 81.4

Principles of immunosuppression

- Principles are the same for all types of organ transplantation
- Aim is to maximise graft protection with minimum of side effects
- Most regimens are based on calcineurin blockade and include steroids and an antiproliferative agent
- Need for immunosuppression is highest in the first three months but indefinite treatment is needed
- Immunosuppression increases the risk of infection and malignancy

Summary box 81.5

Side effects of non-specific immunosuppression

- Infection
 - Transplant recipients are at high risk of opportunistic infection, especially by viruses
 - Bacterial and fungal infections are also common
 - Risk of infection is greatest during first six months
 - Chemoprophylaxis is important for high-risk patients
 - Viral infection may result from reactivation of latent virus or from primary infection
 - Cytomegalovirus is a major problem
 - Pretransplant vaccination against community-acquired infection should be considered
- Malignancy
 - Most types of cancer are more common after transplantation
 - Recipients, especially children, are at risk of post-transplant lymphoproliferative disease (PTLD)
 - There is a very high risk of squamous cancer of the skin and recipients should have regular skin review

Infection

Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. Opportunistic infection is a potential problem in all transplant recipients, but those receiving aggressive immunosuppressive

therapy are most at risk. Chemoprophylaxis is important in high-risk recipients, and early recognition followed by prompt and aggressive treatment of infection is essential in all transplant recipients. Pretransplant vaccination against community-acquired infections should be considered.

Bacterial infection

The risk of bacterial infection is highest during the first month after transplantation. Transplant recipients are, like any patient undergoing major surgery, at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery and are in the intensive care unit with indwelling catheters and lines. After recovery from surgery, the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent, and it is usual to give them chemoprophylaxis for a period of 6–12 months after transplantation.

Viral infection

The risk of viral infection is highest during the first six months after transplantation and the most common problem is CMV infection. CMV disease may arise because of reactivation of latent infection or because of primary infection that can be transmitted by an organ from a CMV-positive donor. Recipients at most risk from CMV infection are those who are CMV seronegative (i.e. those who have not been infected previously with CMV) and receive an organ from a CMV-seropositive donor (about half of all UK donors are CMV seropositive). Unfortunately, matching seronegative donors with seronegative recipients is not practicable. Without prophylaxis, CMV disease typically presents at 4–8 weeks with a high swinging fever, lethargy and leukopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia
- gastrointestinal disease
- hepatitis
- retinitis
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of administration of antiviral agents, most commonly valganciclovir; aciclovir and valaciclovir are cheaper but less effective alternatives. A diagnosis of active CMV infection is confirmed by polymerase chain reaction (PCR) to detect viral DNA in whole blood, and by histological examination of biopsy material. Treatment is with antiviral agents (either oral valganciclovir or i.v. ganciclovir) and is more effective when given pre-emptively on the basis of increased viral load detected by quantitative PCR analysis of peripheral blood.

Herpes simplex virus (HSV) infection is common after transplantation and is usually due to reactivation of latent infection. It causes mucocutaneous lesions around the mouth and sometimes the genitalia. These usually respond to topical treatment with acyclovir, but in severe cases systemic antiviral therapy is needed. Disseminated HSV infection is rare.

BK virus is emerging as an important cause of graft dysfunction after renal transplantation. Infection with BK virus is almost universal during childhood, with latent infection in the epithelium of the urinary tract. Immunosuppression causes lytic BK virus replication with graft involvement in 1–5 per cent of renal transplants. The only effective treatment is to reduce the level of immunosuppression to allow natural immune mechanisms to regain control of the virus.

Herpes zoster infection, as a result of reactivation of latent varicella zoster virus, occurs more frequently in transplant patients and should be treated with systemic antiviral therapy. Primary varicella zoster virus infection (chickenpox) is potentially very serious in immunosuppressed patients but is relatively uncommon as most adults have acquired immunity.

Fungal infection

Pneumocystis jiroveci (previously designated *Pneumocystis carinii* and wrongly classified as a protozoa) is one of the more important fungal infections after transplantation. It occurs during the first few months and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of fungal infection (Figure 81.13). Chemoprophylaxis is highly effective and usually continued for up to six months after transplantation.

Other types of invasive fungal infections are uncommon in renal transplant recipients but infection with *Candida* or *Aspergillus* is more common after other types of organ transplantation. Fungal infection usually occurs in the first three months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

Malignancy

After transplantation, there is an increased risk of developing most types of malignant disease but the risk is particularly high for those types of tumour in which viral infection plays an aetiological role. The increased risk of malignancy is particularly high for skin cancer and post-transplant lymphoproliferative disorder. Most of the skin cancers seen are squamous cell car-

Figure 81.13 Transbronchial lung biopsy from a renal allograft recipient with *Pneumocystis jiroveci* pneumonia. The silver stain used reveals fungal cysts, each containing several intracystic bodies or spores, distributed widely within the biopsy material.

cinomas, but basal cell carcinoma and malignant melanoma are also more common than in the general population. The risk of skin cancer after transplantation rises with age and with exposure to sunlight, and it has been predicted that 50 per cent of transplant patients will develop a skin malignancy within 20 years of transplantation. Patients must be warned of this risk before they undergo transplantation and advised to take precautions to protect their skin from excessive sunlight. They should undergo regular review of their skin to detect early malignancy, and when malignant lesions occur they must be treated promptly and aggressively.

Post-transplant lymphoproliferative disorder is an abnormal proliferation of B lymphocytes, usually in response to Epstein-Barr virus infection. The condition presents in a variety of ways including as an infectious mononucleosis-type illness, as lymphadenopathy or with involvement of extranodal sites such as the tonsils, gastrointestinal tract, lung, liver or the transplanted organ (Figure 81.14). PTLD occurs in around 1–3 per cent of kidney and liver transplant recipients and the incidence is considerably higher in children. Those patients at most risk are those who have received aggressive immunosuppression. PTLD is a serious condition with an overall mortality of up to 50 per cent. If it is identified at an early stage, reduction or cessation

of immunosuppressive therapy may cause disease regression and result in a cure. Chemotherapy is often given and antiviral therapy, surgery and radiotherapy may also have a role in treating established disease. Disseminated PTLT and central nervous system (CNS) involvement have a very poor prognosis.

Transplant patients also have a 300-fold increased risk of developing Kaposi's sarcoma, although this malignancy is still very uncommon after transplantation.

ORGAN DONATION

The number of organs required to satisfy the needs of transplantation far exceeds the number of donor organs available. In the case of renal transplantation in the UK there are approximately 7000 patients waiting for transplantation, but only around 3500 transplants performed annually, which has led to a median waiting time for transplantation of three years. Similar shortages exist for liver and pancreas transplantation. For cardiothoracic organs the shortage is even worse and not all patients who might benefit from transplantation are listed.

Organs may be obtained from living donors or from deceased donors (DD) and DD may be either brainstem-dead heart-beating donors (donation after brain death or DBD donors) or donation after circulatory death (DCD) donors. Living donation is limited to donation of the kidney and, to a much lesser extent, liver or lung lobe. DBD donors provide a majority of organs for transplantation for all organ types although DCD donors provide an increasing number of kidneys, livers, pancreas glands and lungs for transplantation (see Summary box 81.6). The approach to referral and consent for organ donation varies between countries. Some have 'required request' or 'required referral' systems in place where all patients dying in intensive care settings have to be referred for their potential suitability to be organ donors assessed. Some countries (e.g. Austria and Spain) have an 'opt out' or 'presumed consent' system, where the assumption is made that an individual wished to donate their organs for transplantation unless they specifically registered their objection before death. There is debate about whether such a policy alone increases organ donation and a concern expressed by some that individuals who may not have wanted to become organ donors may fail to opt out before death, and that conflict may occur with relatives and next of kin who may oppose organ donation.

Figure 81.14 (a) Intestinal post-transplant lymphoproliferative disease (PTLD). Note multiple lesions in terminal ileum and colon. (b) Atypical B lymphocytes stained positive with a probe for Epstein-Barr virus (EBV) DNA (courtesy of C Watson, R Chavez-Cartaya and D Wight).

Summary box 81.6

Overcoming the shortage of organs for transplantation

- Maximising donation after brain-death (DBD) donation
- Use of marginal DBD deceased donors
- Use of donation after circulatory death (DCD) donors
- Increased use of split liver transplantation
- Increased living donor kidney (and liver) transplantation

Donation after brain death donors

The majority of DD organs are obtained from patients in whom brainstem death has been diagnosed. Such donors were previously called 'heart-beating deceased donors' and in most brain death results from stroke or traumatic head injury. Brain

death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries, it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of patients with irreversible brain damage on life support when there was no prospect for recovery. It was not in the interest of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain death had major implications for organ transplantation as it allowed the possibility for removal of viable organs from brain-dead patients before their circulation failed.

In the UK and many other countries, brain death is defined in terms of permanent functional death of the brainstem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brainstem. A diagnosis of brainstem death should be considered only when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require ventilatory support. Particular care must be taken to ensure that muscle relaxant agents and drugs with known CNS depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brainstem death must also be excluded. When the necessary preconditions have been satisfied, formal clinical assessment of the brainstem reflexes can be undertaken (Table 81.5). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brainstem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK, there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brainstem death. Particular care is required in the diagnosis of brainstem death in neonates and infants.

Donation after circulatory death donors

The number of potential DBD donors has remained relatively static or even declined as a result of changes in neurosurgical practice and improved road safety. To address the rising demand for organ transplantation there has been a major trend towards increasing use of organs from DCD donors.

DCD donors can be grouped according to the Maastricht classification as follows:

- category 1: dead on arrival at hospital;
- category 2: resuscitation attempted without success;
- category 3: 'awaiting cardiac arrest' after withdrawal of support;
- category 4: cardiac arrest while brain dead;
- category 5: cardiac arrest and unsuccessful resuscitation in hospital.

Maastricht categories 1, 2 and 5 donors are sometimes referred to as uncontrolled DCD donors. The warm ischaemic time of organs from these three categories of donor is usually longer and less predictable than in the case of categories 3 and 4 (controlled) donors. The majority of DCD donor organs used

Table 81.5 Clinical testing for brainstem death.

Absence of cranial nerve reflexes	Pupillary reflex Corneal reflex Pharyngeal (gag) and tracheal (cough) reflex Oculovestibular (caloric) reflex
Absence of motor response	The absence of a motor response to painful stimuli applied to the head/face and the absence of a motor response within the cranial nerve distribution to adequate stimulation of any somatic area is an indicator of brainstem death. The presence of spinal reflexes does not preclude brainstem death
Absence of spontaneous respiration	After preoxygenation with 100% O ₂ for at least 5 minutes, the patient is disconnected from the ventilator for 10 minutes to confirm absence of respiratory effort, during which time the arterial PCO ₂ level should be >8 kPa (60 mmHg) to ensure adequate respiratory stimulation. To prevent hypoxia during the apnoeic period, O ₂ (6 L/min) is delivered via an endotracheal catheter

for transplantation in the UK, US and several other European countries are from controlled (category 3) donors who have died in intensive care after planned withdrawal of futile cardiorespiratory support.

Kidneys may be also be recovered from carefully selected patients who are dead on arrival at the hospital or who have died following unsuccessful resuscitation. In Spain and France most DCD kidneys are obtained from uncontrolled donors.

Evaluation of the deceased donor

After a deceased donor has been referred to the transplant team with a view to organ donation, the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be carefully scrutinised and evidence sought of risk factors for human immunodeficiency virus (HIV), such as intravenous drug abuse. The presence of Creutzfeldt-Jakob disease is an absolute contraindication to organ donation. Organs from HIV-infected donors should not be used for transplantation, except sometimes in recipients who are already infected by the HIV virus. Hepatitis B infection (in most countries) and active systemic sepsis, e.g. major abdominal infection, are contraindications to donation. The presence of malignancy within the past five years is usually an absolute contraindication to organ donation with the exceptions of primary tumours of the CNS, non-melanotic tumours of the skin and carcinoma *in situ* of the uterine cervix. If there are no general contradictions to organ donation, consideration is then given to organ-specific selection criteria.

Because of the high demand for donor organs there has been a progressive relaxation in the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation.

The organs to be donated should generally be free from primary disease. Potential kidney donors should have a reasonable urine output and relatively normal serum urea and creatinine, although acute terminal elevations are acceptable. Liver donors should not have hepatic disease, although impaired liver function tests are common in deceased donors and do not necessarily preclude donation. Heart donors should have a normal electrocardiogram and, in doubtful cases, echocardiography may be necessary. For lung donors the chest radiograph and gas exchange should be satisfactory, and bronchial aspirates should be free from fungal and bacterial infection. Elevations of blood glucose and serum amylase are not uncommon in deceased donors and do not preclude pancreas donation. The use of organs from suboptimal or 'marginal' deceased donors has increased markedly in an attempt to address the demand for transplantation. The definition of a marginal donor depends on the organs being considered for transplantation and varies between countries. In the case of kidney transplantation a marginal donor is defined in the United States as a donor age >60 years or one between the ages of 50 and 60 years with two of the following: hypertension, death from stroke and a terminal creatinine of >132 mmol/L. Organs from 'marginal donors' generally lead to less satisfactory transplant outcomes than those from standard donors.

Organ recovery from deceased donors

In DBD donors, once brainstem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be recovered. Brainstem death produces profound metabolic and neuroendocrine disturbances leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Inotropic support is given and there may be a role for the use of tri-iodothyronine (T3) and argipressin.

Recovery of multiple organs from a DBD donor requires cooperation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy is used to obtain access. After dissection of the organs to be recovered, they are perfused *in situ*. The heart is perfused with cold cardioplegia solution via a cannula in the ascending aorta and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are vented from the left atrial appendage and the inferior vena cavae. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised followed by the liver and pancreas and then the kidneys, either en bloc or separately. The extent to which the abdominal organs are dissected prior to cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection prior to cold perfusion and complete the dissection of the abdominal organs *in situ* or on the back table after the organs have been removed en bloc. During recovery of the liver, care is taken to ensure that if there is an aberrant hepatic artery arising from the superior mesenteric artery it is included in the aortic patch. An adult donor liver cannot be transplanted into a child because of the size mismatch, and there are insufficient deceased paediatric donor livers available for transplantation. One solution is to undertake split liver transplantation, which was first performed by Pichlmayr in 1988. The liver from a deceased donor is split and the left lobe or left

Figure 81.15 An adult liver may be split (according to Couinaud's segments) so that the left lateral segment (segments II and III) can be transplanted into a child and the right lobe (together with segment IV) can be transplanted into an adult. CHD, common hepatic duct; FL, falciform ligament; HA, hepatic artery (on aortic patch); IVC, inferior vena cava; LHD, left hepatic duct; LHV, left hepatic vein; LPV, left portal vein; RHA, right hepatic artery; RPV, right portal vein.

lateral segments are used for a paediatric recipient and the right lobe is used for an adult recipient (Figure 81.15).

When removing the donor kidneys care is taken to ensure that any polar renal arteries are included on an aortic patch with the renal artery (Figure 81.16). In older kidney donors with atherosclerosis the aortic segment may be too diseased to use as an arterial patch and the donor renal artery and any polar arteries are divided shortly after their origin and if necessary reconstructed prior to implantation (Figure 81.17). In the case of the pancreas, a Y graft of donor iliac artery is excised and used to reconstruct the divided splenic and superior mesenteric arteries of the graft prior to implantation (Figure 81.18).

In DCD donors there is an inevitable period of warm ischaemia (up to 45 minutes is acceptable) between the diagnosis of death (cardiorespiratory arrest) and cold perfusion of the organs. The aim during organ recovery is to minimise the period of

Figure 81.16 Deceased donor kidney with multiple renal arteries on an aortic patch. The aortic patch has been shortened to limit the length of the anastomosis needed when joining the donor patch to the side of the recipient external iliac artery (Medical Photography, Addenbrooke's Hospital).

Figure 81.17 Deceased donor kidney from elderly (>70 years) donor illustrating the technical challenges of using kidneys from marginal donors. The aorta shows severe atherosclerosis with extensive plaque formation and ulceration and is not suitable for use as an aortic patch. A lower polar artery has already been divided. The two arteries can be joined together prior to implantation or implanted separately.

warm ischaemia although the approach used differs according to whether the donor is a controlled or uncontrolled DCD donor. It is important to note that only around 50 per cent of all patients considered as potential controlled DCD donors have a cardiorespiratory arrest within the period of time (usually 2 hours) considered practicable for the surgical team to stand by for organ recovery. After cardiorespiratory arrest there is an obligatory 'hands off' period before certification of death of at least 5 minutes before the surgical procedure for organ recovery can begin. If not already in the operating theatre, the DCD donor is transferred immediately to the operating room and the abdomen opened to allow rapid cannulation of the aorta and cold perfusion of the organs to be recovered. In the case of uncontrolled DCD donors the warm ischaemic time can be minimised by rapid insertion of a double balloon catheter introduced into the aorta via a femoral cut-down and used to cool the kidneys *in situ*

Figure 81.18 Donor pancreas viewed from the posterior aspect after preparatory bench surgery. The duodenal component of the graft has been sutured closed proximally and distally and a Y graft of donor iliac artery used to reconstruct the divided splenic and superior mesenteric arteries. The bile duct (ligated) and portal vein are anterior and not seen in this view.

by chilled perfusate preferably within 30 minutes of circulatory arrest (Figure 81.19). This allows time to gain consent from relatives for organ donation to proceed if it is not already available and to assemble the surgical team for organ recovery.

After removal from the donor, the organs may undergo a further flush with chilled preservation solution before they are placed in double or triple sterile bags and stored at 4°C by immersion in ice while they are transported to the recipient centre and await implantation. Once the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for confirmation of tissue type and use in the cross-match test.

Various organ preservation solutions are available for flushing organs before cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Euro-Collins solution, but there are many others. The use of UW solution (Table 81.6) (developed by Belzer and colleagues in Wisconsin, USA) is particularly effective for liver grafts, and after perfusion with UW the liver can be stored safely for up to 24 hours. The length of time for which an organ can be stored before transplantation varies depending on the type of organ (Table 81.7). Although minimising the duration of organ storage is important for all organs, it is essential that organs from DCD donors are transplanted with the minimum possible cold storage time. Most organs for transplantation are stored by static cold storage in an ice box. However, there is a recent trend towards storing deceased donor kidneys by pulsatile machine perfusion where the kidneys are placed inside a purpose-designed perfusion machine that pumps cold preservation solution through the renal artery in an attempt to reduce ischaemic injury. Machine perfusion can be started immediately

Figure 81.19 *In situ* perfusion of kidneys in a non-heart-beating donor (donation after cardiac death (DCD)). A double-balloon aortic catheter is introduced through a groin incision and 10–15 litres of chilled preservation solution is administered. The perfusate is vented through a Foley catheter introduced into the femoral vein.

after kidney recovery or as soon as practicable thereafter and is usually continued until the time of implantation. The benefit of machine perfusion over simple cold storage is currently the subject of considerable debate.

Living kidney donors

Living-donor renal transplants account for around 30 per cent of the total renal transplant activity in the UK, but in some countries (notably the Scandinavian countries and the US) this figure is much higher (>50 per cent). The justification for living-donor renal transplantation is based on the shortage of deceased donor transplants and the superior results obtained. Traditionally most living-donor transplants were between genetically related individuals. However, living donor kidney transplants performed between genetically unrelated individuals also fare better than even well-matched deceased donor grafts, and this observation gave rise to a steady increase in living unrelated kidney transplantation activity, usually between spouses or partners. It is essential to ensure that in all cases of living donation the prospective donor is fully informed and is free from coercion to donate and that the risk to the donor is small.

In the UK, all living donor transplants (irrespective of whether they are genetically related or not) require prior approval by the Human Tissue Authority (HTA). An independent person (one not associated with the transplant team) approved by the HTA must provide confirmation to the HTA that the donor and recipient understand the implications of the proposed operation and that there is no evidence of coercion or financial inducement.

Live donation should proceed only after the prospective donor has undergone rigorous assessment to ensure that they are suitable. Before the donation, it is essential to perform imaging (usually magnetic resonance angiography or computed tomography-guided angiography), to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery (10 per cent of kidneys have two or more renal arteries), it is usually chosen for transplantation because the longer left renal vein simplifies the transplant operation. The presence of multiple renal arteries does not necessarily preclude donation although implantation of living donor kidneys with multiple renal arteries may increase the chances of vascular complications developing after implantation.

Live donor nephrectomy was historically undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. In most transplant units, nephrectomy is now undertaken laparoscopically (totally laparoscopic or hand-assisted). Laparoscopic nephrectomy is associated with less wound pain in the donor, allows more rapid mobilisation after surgery and reduces hospital stay. Initial concerns that kidneys removed by the laparoscopic technique may have more ureteric complications after implantation have proven unfounded. After removal from the donor the kidney is flushed immediately with chilled organ preservation solution (Figure 81.20). The mortality rate for live donation is less than 0.05 per cent, and around one-half of reported deaths are due to pulmonary embolic disease so it is essential to ensure prophylaxis to reduce deep-vein thrombosis (DVT). The major complication rate after live donor nephrectomy is <5 per cent: potential complications include haemorrhage requiring blood transfusion or surgery, infection (chest, abdomen, renal tract and wound), damage to an intra-abdominal viscus, adverse reaction to drugs and anaesthetic agents, and DVT and pulmonary embolus.

Figure 81.20 After removal from the donor kidney is flushed with chilled organ preservation solution and, if necessary, stored briefly on ice until transplanted into the recipient.

In the long term, kidney donors may be at increased risk from hypertension and donors should have their blood pressure and urine checked annually.

Around 35 per cent of potential living donor transplant recipients will be ABO blood group incompatible with their intended donor and until recently this precluded transplantation. However, there are now two potential solutions to this problem. The first is 'paired donation' where incompatible donor/recipient pairs exchange kidneys between pairs to allow ABO-compatible transplantation (Figure 81.21). Recruitment of more than two pairs to facilitate 'pooled donation' increases the likelihood of matching donors with compatible recipients and while such schemes pose considerable logistic challenges they are now operating successfully in several countries. An alternative approach is to transiently deplete ABO antibodies from potential recipients by passing their blood through special absorption columns or by performing plasmapheresis along with administration of pretransplant immunosuppressive agents (Figure 81.22). Perhaps surprisingly, graft outcome following desensitisation is similar to that after paired donation. Both paired donation and antibody depletion strategies are also potentially applicable to recipients in whom HLA antibodies preclude transplantation from an intended living donor, but graft survival

Figure 81.21 Paired living donor kidney transplantation. Paired donation allows patients with willing but blood group-incompatible donors to be transplanted by pairing them with other incompatible donor-recipient pairs. In the example shown, the two willing donors are incompatible with their intended recipient (blood groups A to B and B to A) but by paired donation each recipient can receive an ABO-compatible kidney transplant (blood groups A to A and B to B).

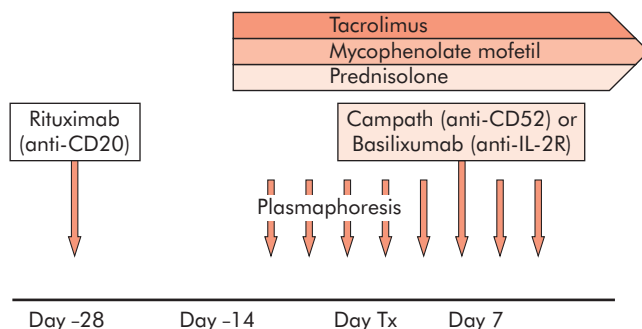

Figure 81.22 Typical desensitisation protocol for ABO or human leukocyte antigen (HLA) antibody incompatible live donor kidney transplant.

after depletion of HLA antibodies is lower than when the recipient receives a kidney from an HLA antibody-compatible donor.

Living liver donors

Living donor liver transplantation is now undertaken in a number of transplant centres worldwide and is relatively common practice in some countries where deceased donation is not practised for cultural or religious reasons, notably Japan and Korea. The concept was first pioneered to allow children to receive the left lobe or left lateral segment from an adult donor and has been very successful. It has now been extended to adult-to-adult live liver transplantation (Figure 81.23). The majority of such transplants require a right liver lobe to provide adequate hepatic function. For adult-to-adult live liver donation, the donor procedure has a reported mortality rate of around 0.5 per cent and a major complication rate of up to 15 per cent. One of the more common donor complications is bile leak.

Living donors: other organs

Occasionally, living donors have provided segments of pancreas, small bowel and lung for transplantation, but this is more controversial. In the United States, living donor combined kidney and segmental pancreas transplantation has been undertaken to treat insulin-dependent diabetics with end-stage renal disease. In occasional patients, living-donor small bowel transplantation has been performed using a small bowel graft, which comprises a length of around 1.5 m of ileum. Finally, a small number of living-donor segmental lung transplants have been performed. To provide sufficient pulmonary tissue without compromising the donor, it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

Resumption of function following organ transplantation

It is crucial that following heart, lung or liver transplantation the transplanted organ resumes satisfactory function immediately. If primary non-function occurs, the only option is rapid retransplantation. After kidney, pancreas or small bowel transplantation, immediate graft function is desirable but not vital. The factors that determine the functional integrity of a transplanted organ are shown in Summary box 81.7. Kidneys

Summary box 81.7

Factors determining organ function after transplantation

- Donor characteristics
 - Extremes of age
 - Presence of pre-existing damage in transplanted organ
 - Haemodynamic and metabolic instability
- Procurement-related factors
 - Warm ischaemic time
 - Type of preservation solution
 - Cold ischaemic time
- Recipient-related factors
 - Technical factors relating to implantation
 - Haemodynamic and metabolic stability
 - Immunological factors
 - Presence of drugs that impair transplant function

Figure 81.23 Living donor hepatectomy. A CUSA (cavitron ultrasonic aspirator) is being used to divide the right and left lobes of the liver so that the right lobe can be transplanted into an adult recipient.

obtained from DCD donors invariably suffer a variable degree of ischaemic damage, and delayed graft function is more common (typically 50 per cent for category 3 DCD donors) than for kidneys obtained from DBD deceased donors (typically 25 per cent). Irreversible ischaemic necrosis occasionally occurs and the graft never functions adequately (primary non-function). However, graft survival results for kidneys from controlled DCD kidneys are similar to those obtained from DBD deceased donors. Livers obtained from DCD donors have an increased incidence of primary non-function and of biliary complications, including biliary anastomotic strictures, bile leak and ischaemic cholangiopathy.

KIDNEY TRANSPLANTATION

Patient selection

Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life for them than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. Transplantation is also more cost-effective than dialysis and improves patient survival.

In the UK, around 100 people per million of the population develop end-stage renal disease, and the incidence increases with age. The causes of end-stage renal disease are numerous and include the following:

- glomerulonephritis;
- diabetic nephropathy;
- hypertensive nephrosclerosis;
- renal vascular disease;
- polycystic kidney disease;
- pyelonephritis;
- obstructive uropathy;

- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic disease (oxalosis, amyloid).

Frequently, the primary cause of end-stage renal disease is uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before acceptance as suitable candidates on the transplant waiting list, a transplant surgeon and nephrologist should formally assess all patients. A significant number of patients are likely to be considered unsuitable for renal transplantation because of major comorbid disease, especially cardiovascular disease. In the UK, around 30–40 per cent of the dialysis population are on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Many of the glomerulonephritides (especially IgA, focal segmental glomerulosclerosis, and mesangiocapillary glomerulonephritis types I and II) may recur in a kidney transplant, and sometimes can lead to early graft failure (especially focal segmental glomerulosclerosis). In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades, and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to renal transplantation, but inevitably older patients (over the age of 65 years) are less likely to be considered suitable candidates because of major cardiovascular and other comorbid disease.

A careful assessment of comorbid disease that might significantly reduce the chances of successful outcome after transplantation is essential (Summary box 81.8). Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation, it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is intractable renal sepsis or very large polycystic kidneys that intrude into both iliac fossae is native nephrectomy required before transplantation (Figure 81.24). Finally, the prospective transplant recipient must be deemed able to cope with the psychological consequences of transplantation and likely to comply with immunosuppressive therapy.

Summary box 81.8

Evaluation of potential recipients for organ transplantation

- Evaluation undertaken by appropriate multidisciplinary team including surgeon and physician
- Determine presence of comorbid disease
- Exclude malignancy and systemic sepsis
- Evaluate against organ-specific criteria for transplantation
- Determine probable ability to cope psychologically with transplant and comply with immunosuppression
- Evaluate need for any preparative surgery needed to facilitate transplantation
- Optimise recipient condition prior to transplantation

Figure 81.24 Computed tomography scan of a patient with very large polycystic kidneys that extend well into both iliac fossa. The patient requires removal of one of the polycystic kidneys to make room for a subsequent renal transplant. Nephrectomy should be performed several weeks before transplantation.

Immunosuppressive therapy impairs the protective response to both malignancy and infection. Consequently, pre-existing malignancy is an absolute contraindication and, even after curative treatment, transplantation should not usually be considered for at least three years. Similarly, the presence of active infection is a contraindication to transplantation.

Technique of renal transplantation

The transplant kidney is placed in the iliac fossa, in the retroperitoneal position, leaving the native kidneys *in situ*. After induction of general anaesthesia, a central venous line and a urinary catheter are inserted. It is helpful to distend the bladder with saline containing methylene blue to allow it to be identified with certainty prior to ureteric implantation. A curved incision is made in the lower abdomen and, after dividing the muscles of the abdominal wall, the peritoneum is swept upwards and medially to expose the iliac vessels. These are dissected free so that they can be controlled with vascular clamps. The kidney is then removed from ice and the donor renal vein is anastomosed

end-to-side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is anastomosed end-to-side to the external iliac artery (Figure 81.25a). If the donor renal artery lacks an aortic patch, as in the case of a living-donor transplant, it may be preferable to anastomose the donor artery end-to-end to the recipient internal iliac artery (Figure 81.25b). While the vascular anastomoses are being undertaken, the kidney is kept cold by application of topical ice.

Following completion of the venous and arterial anastomoses, the vascular clamps are removed and the kidney is allowed to reperfuse with blood. The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (Figure 81.26). This is achieved by direct implantation of the ureter into the dome of the bladder with a mucosa-to-mucosal anastomosis followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel, the Lich–Gregoir technique. A double-J ureteric stent should be left *in situ*, to reduce the risk of urine leak or early obstruction, and removed after several weeks by cystoscopy. If the donor ureter is too short to reach the bladder, the native ureter can be divided

Figure 81.26 Ureteric implantation by direct anastomosis to a small cystostomy. (a) Lich–Gregoir technique; (b) Leadbetter–Politano technique.

Figure 81.25 Implantation of renal allograft. (a) The renal artery on a Carrel patch is anastomosed to the external iliac artery. (b) The renal artery is anastomosed end-to-end to the internal iliac artery. IVC, inferior vena cava.

and the distal segment anastomosed to the ureter or renal pelvis of the donor kidney. The proximal segment of the native ureter can usually be ligated and the native kidney left *in situ* without causing a problem. Before closing the transplant wound, it is very important to ensure that the kidney is lying in a satisfactory position without kinking or torsion of the renal vessels. In small children receiving an adult donor kidney, the abdomen is opened through a midline incision and the graft is placed intra-abdominally with anastomosis of the renal vessels to the aorta and vena cava.

Technical complications

Vascular complications

The incidence of vascular complications after renal transplantation is quite low. Renal artery thrombosis occurs in approximately 1 per cent of cases. Renal vein thrombosis is more common (up to 5 per cent of cases) and, although sometimes due to technical error, the aetiology is often uncertain. It presents during the first week after transplantation with sudden pain and swelling at the site of the graft. The diagnosis is confirmed by Doppler ultrasonography. Urgent surgical exploration is indicated, and in most cases transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimised by giving low-dose heparin or aspirin prophylaxis. Renal artery stenosis usually presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10 per cent of grafts and is diagnosed by angiography. Renal artery stenosis is best treated by angioplasty, but if angioplasty fails or is not technically possible then the condition can be treated successfully by open surgery and vascular reconstruction.

Urological complications

Urological complications occur in around 5 per cent of patients in the early post-transplant period, but their incidence can be reduced markedly by leaving a temporary ureteric stent *in situ*. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and leakage of urine from the wound and usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the ipsilateral native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include technical error, external pressure from a haematoma or lymphocele and ischaemic stricture. Ureteric obstruction presents with painless deterioration in graft function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous antegrade nephrostomy and insertion of a stent. Some ureteric strictures may be amenable to treatment by balloon dilatation but most are best treated by surgical intervention, reimplanting the donor ureter into the bladder or anastomosing it to the native ureter.

Lymphocele

Peritransplant lymphocoeles are usually asymptomatic, but occasionally they become large enough to cause ureteric obstruction or oedema of the ipsilateral leg. Initial treatment is usually by ultrasound-guided percutaneous drainage. In the case of large or recurrent lymphocoeles, surgical intervention may be needed to drain a persistent lymphocele into the peritoneal cavity, and

this can often be achieved by an ultrasound-guided laparoscopic approach.

Investigation of graft dysfunction

Graft dysfunction (Summary box 81.9) during the early postoperative period is a common problem. Possible causes are:

- acute tubular necrosis;
- arterial/venous thrombosis;
- urinary leak/obstruction;
- CNi toxicity;
- hyperacute/accelerated acute rejection.

Summary box 81.9

Causes of allograft dysfunction

- Early
 - Primary non-function (irreversible ischaemic damage)
 - Delayed function (reversible ischaemic injury)
 - Hyperacute and acute rejection
 - Arterial or venous thrombosis of the graft vessels
 - Drug toxicity (e.g. CNi toxicity)
 - Infection (e.g. CMV disease in graft)
 - Mechanical obstruction (ureter/common bile duct)
- Late
 - Chronic rejection
 - Arterial stenosis
 - Recurrence of original disease in graft (glomerulonephritis, hepatitis C)
 - Mechanical obstruction (ureter, common bile duct)

Delayed graft function (defined as the need for dialysis post-transplantation) as a result of acute tubular necrosis occurs in around 25 per cent of kidneys from DBD and up to 50 per cent of kidneys from DCD donors, but is uncommon (<5 per cent) following living-donor transplantation. Often, recipients produce significant volumes of urine from their native kidneys, making the diagnosis of delayed graft function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the urinary catheter should be irrigated in case it is occluded by a blood clot. Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation as it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. Renal radionuclide scanning provides information on renal perfusion and excretion and may be helpful but is used infrequently. If graft dysfunction is still present after several days, it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present and then to repeat the investigation every week or so until graft function occurs. CNi toxicity may cause graft dysfunction and it is important to monitor CNi blood levels to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation, but a small number of grafts (<5 per cent) suffer primary non-function (i.e. never function).

Allograft dysfunction developing late (>1 month after transplant) may be due to:

- acute/chronic rejection;
- drug toxicity;
- ureteric obstruction (lymphocoele/ureteric stricture);
- recurrent disease;
- urinary tract infection.

Blood levels of cyclosporine or tacrolimus are assessed to ensure that they are not unduly elevated, and ultrasound examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous antegrade pyelography and treated as outlined above. If there is uncertainty about the cause of graft dysfunction, transplant biopsy should be performed to establish whether allograft rejection is present.

Outcome after transplantation

The results of organ transplantation (Summary box 81.10) are generally defined in terms of patient and graft survival. Patient survival after deceased donor renal transplantation is >95 per cent at one year and >85 per cent at five years. Graft survival is around 90 per cent at one year and 80 per cent at five years. Graft survival after a second transplant is only marginally worse than after a first graft. After living-related kidney transplantation, overall graft survival is around 95 per cent at one year and 85 per cent at five years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life of grafts obtained from living donors is substantially longer than that of DD grafts:

- deceased donor grafts, 13 years;
- living-unrelated grafts, 15 years;
- living-haploidentical grafts, 16 years;
- living-identical sibling grafts, 27 years.

Summary box 81.10

Outcome after transplantation

- Transplantation improves the quality and duration of life in most recipients
- Transplant outcome has improved progressively over the last two decades and continues to improve
- Improved outcome is due to better immunosuppression, organ preservation, chemoprophylaxis and technical advances
- Graft survival after kidney, liver and heart transplantation is >90 per cent at one year and >80 per cent at five years
- The results of lung and small bowel transplantation are less good
- Chronic rejection is the most common cause of graft failure after all types of solid-organ transplant
- Recurrence of the original disease necessitating transplantation may also lead to graft failure
- Death with a functioning transplant from cardiovascular disease is relatively common
- Up-to-date transplant outcomes for the different organs can be found at the online national and international transplant databases (see end of chapter for website addresses)

If a kidney transplant fails late after transplantation, the graft can often be left *in situ* and immunosuppression stopped, but transplant nephrectomy may be indicated if the graft is causing symptoms. The operation is undertaken via the original wound, but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival, it is important to consider the extent to which transplantation improves the physical and mental well-being of the patient and allows them to lead a satisfactory social life. In the case of kidney, as in other types of solid organ transplant, successful transplantation undoubtedly leads to a substantial improvement in quality of life. However, although some recipients return to a normal or near-normal life, others fare much less well and, for the group overall, the quality of life after transplantation falls short of that seen in normal healthy individuals. Renal transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.

PANCREAS TRANSPLANTATION

Successful pancreas transplantation restores normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels in diabetes reduces the progression of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks posed by both the transplant procedure itself and the immunosuppressive therapy required to prevent graft rejection. For most patients with diabetes, the additional risks associated with pancreas transplantation and immunosuppression are such that the operation can be justified only when kidney transplantation for diabetic nephropathy is also being undertaken. The only additional risks of pancreas transplantation in such patients relate to the transplant operation itself. In the United States, around one-half of all diabetic patients undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called simultaneous pancreas and kidney (SPK) transplantation. Pancreas transplantation is sometimes performed in patients who have already undergone successful kidney transplantation, pancreas after kidney (PAK) transplantation. Occasionally, pancreas transplantation alone (PTA) can be justified to treat life-threatening diabetic complications such as hypoglycaemic unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type I diabetes who are relatively young (under the age of 55 years) and do not have advanced coronary artery disease or peripheral vascular disease. Investigation of the heart's response to stress, either using echocardiography or nuclear medicine imaging is mandatory.

Surgical technique

The whole pancreas gland together with a segment of duodenum is transplanted, essentially as pioneered by Lillehei in 1966. Segmental pancreas transplantation is performed only occasionally. SPK transplantation is usually performed through a midline incision (Figure 81.27). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the

Figure 81.27 Pancreas transplant operation with enteric drainage of the exocrine secretion via a duodenoenterostomy. A 'Y' graft using donor iliac artery is usually used to reconstruct the divided splenic and superior mesenteric arteries of the graft prior to implantation.

kidney graft is placed on the left side. The donor vessels of the pancreas graft are anastomosed to the recipient iliac vessels and the exocrine secretions are most commonly dealt with by anastomosing the graft duodenum to the small bowel (enteric drainage) often via a roux-en-Y loop although the duodenum may sometimes be anastomosed to the bladder (urinary drainage). The pancreas graft functions immediately after revascularisation, although supplementary insulin may be required for a few days. Technical complications usually occur early and include vascular thrombosis of the graft (5 per cent) and duodenal anastomotic leaks. Wound infection occurs in up to 10 per cent of patients, and intra-abdominal infection is relatively common. The specific complications of enteric drainage include intra-abdominal sepsis and adhesive small intestinal obstruction. Bladder drainage of the exocrine pancreas may result in the following complications:

- bladder/duodenal anastomotic leaks;
- cystitis (owing to effect of pancreatic enzymes);
- urethritis/urethral stricture;
- reflux pancreatitis;
- urinary tract infection;
- haematuria;
- metabolic acidosis (due to loss of bicarbonate in the urine).

Urinary drainage of the pancreas has the advantage that urinary amylase levels can be used to monitor for graft rejection. However, after bladder drainage, urinary complications are common, and in around 20 per cent of cases their severity necessitates conversion to enteric drainage. Most centres now prefer primary enteric drainage after SPK transplantation. Acute rejection after SPK transplantation is relatively common (10–20 per cent) and if detected early responds to treatment with steroids. Since it usually involves both the kidney and pancreas graft, serum creatinine can be used as a surrogate marker for pancreas graft rejection. Serum lipase and amylase levels are useful indications of pancreas graft inflammation of which acute rejection is one cause. Urinary drainage has the advantage, after PTA

and PAK transplantation, of allowing pancreas graft rejection to be monitored by serial measurement of urinary amylase. A fall in urinary amylase is indicative of acute rejection. Elevation of blood glucose level is a late feature of acute rejection and often indicates the process is beyond reversal.

Results of pancreas transplantation

The principal aim of pancreas transplantation is to prolong life in diabetic patients who otherwise have a high mortality at ten years after receiving a kidney transplant alone. It also provides freedom from insulin treatment and improves quality of life.

The results of pancreas transplantation have improved significantly over the last decade. After SPK transplantation, the one-year patient survival rate is greater than 95 per cent and the one-year graft survival rates for pancreas and kidney grafts are 85 and 95 per cent, respectively. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SPK transplantation in patients with diabetic nephropathy is at least as good as after kidney transplant alone in this group. The results of PTA are not as good as after SPK transplantation (one-year pancreas graft survival 75 per cent) because acute rejection is more difficult to monitor in the absence of a kidney allograft.

Transplantation of isolated pancreatic islets

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanically disrupting the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density-gradient centrifugation and can be delivered into the recipient liver (the preferred site for transplantation) by injection into the portal vein. Until recently, human islet transplantation had been performed intermittently and with very disappointing results. However, in 2000, Shapiro and colleagues in Edmonton, Canada, reported success with islet transplantation in seven patients with type I diabetes. Sequential islet transplantation from two or three donor pancreas glands was required to produce insulin independence, and although the long-term success is less than initially hoped for, some patients remained free from exogenous insulin and other units are now undertaking islet transplantation with variable results.

As an alternative to preventing islet rejection through immunosuppressive therapy, attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semipermeable membranes. The protective membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leukocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used and bioartificial pancreas grafts containing xenogeneic islets are currently under evaluation.

LIVER TRANSPLANTATION

Starzl first attempted liver transplantation in 1963 and, by 1967, had achieved prolonged survival. The first liver transplant

performed outside the US was performed in Cambridge, UK by Calne in 1968. Throughout the 1970s, liver transplantation remained a hazardous procedure that frequently failed. However, since then, the results have progressively improved as a result of better patient selection, improved immunosuppression and chemoprophylaxis, better organ preservation, refinements in the operative technique, and advances in per- and postoperative management.

Indications and patient selection

The indications for liver transplantation fall into four groups:

- 1 cirrhosis;
- 2 acute fulminant liver failure;
- 3 metabolic liver disease;
- 4 primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults the most common causes are alcoholic liver disease, viral liver disease (hepatitis C in Europe and the US and hepatitis B in some other countries), non-alcoholic steatohepatitis, primary biliary cirrhosis and sclerosing cholangitis. In children, who account for around 10–15 per cent of all liver transplants, biliary atresia is the most common indication for transplantation. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10 per cent of liver transplant activity and is usually viral or drug induced (e.g. paracetamol overdose in the UK). There are a variety of metabolic diseases for which transplantation offers the prospect of cure. These include Wilson's disease, oxalosis and familial amyloid polyneuropathy. Primary hepatic malignancy is more common in patients with cirrhosis, especially virally induced disease, and may be best treated by transplantation because the field changes in the cirrhotic liver predispose to further primary malignancies. Cholangiocarcinoma has a high recurrence rate and is seldom an indication for liver transplantation.

Technique of liver transplantation

A transverse abdominal incision with a midline extension is usually made and the diseased liver is mobilised (Figure 81.28). Because of portal hypertension, the recipient hepatectomy is often the most difficult part of the operation, especially if there has been previous upper abdominal surgery. The common bile

Figure 81.28 (a) Incision used for liver transplantation. (b) Completed implantation. The anastomoses, in order of performance, are: (1) supra-hepatic cava; (2) infrahepatic cava; (3) portal vein; (4) hepatic artery; (5) bile duct.

duct is divided, as is the hepatic artery. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided, allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of venovenous bypass. The bypass circuit delivers blood from the inferior vena cava and/or portal vein and back to the heart via a cannula inserted into the internal jugular vein. After placing the donor liver in position, the supra- and infrahepatic caval anastomoses are performed. The portal vein and the hepatic arterial anastomoses are then completed and the graft is reperfused. Finally, biliary drainage is re-established usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile duct to Roux loop anastomosis. An alternative caval preservation technique of liver transplantation allows the recipient liver to be removed without cross-clamping the vena cava and the donor liver to be implanted using a 'piggyback' technique onto the recipient hepatic veins or using a side-to-side cavo-cavoplasty.

Many patients undergoing liver transplantation are extremely ill, and the surgery involved can be very technically demanding. Optimal perioperative management is crucial to a successful outcome and presents a major challenge. Blood loss during and after the transplant procedure can be very considerable, and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the transplant period and corrected with appropriate clotting factors. Many centres routinely use a thromboelastography to perform dynamic assessment of coagulation (Figure 81.29). In the most widely used system (rotational thromboelastography) this involves placing a blood sample in a small cuvette and then inserting a sensor pin that is subjected to rotational torsion and as clot between the cuvette and the pin forms, the resulting signal is displayed graphically and indicates the speed and strength of clot. Various modifications can be made to the test conditions to maximise the information provided.

Figure 81.29 Thromboelastogram situated in the operating theatre and used to measure coagulation serially throughout the liver transplant procedure and guide administration of blood products.

Technical complications

Haemorrhage

Meticulous haemostasis during the transplant operation is important in order to minimise the risk of early haemorrhage. It may be necessary, occasionally, to pack the peritransplant area for 2–3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive perihepatic haematoma may be required to avoid secondary infection.

Vascular complications

Hepatic artery thrombosis may occur spontaneously or as a result of acute rejection and is more common in paediatric recipients and in adults with primary sclerosing cholangitis. It may present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasonography or angiography is used to confirm the diagnosis, and urgent retransplantation is usually required. Portal vein thrombosis is rare and presents with the features of portal hypertension.

Biliary complications

Biliary leaks are now relatively uncommon and biliary stenosis is the more common problem. It usually occurs within the first few months of transplantation and is managed by endoscopic dilatation and stenting or by surgical correction.

Outcome after liver transplantation

The outcome after liver transplantation depends on the underlying liver disease and the best results are seen in patients with chronic liver disease (Figure 81.30). Patients undergoing transplantation as a result of acute liver failure have a higher mortality in the early post-transplant period because of multi-organ failure, but those who make a satisfactory recovery have

Figure 81.30 Outcome after liver transplantation according to the initial liver disease. Patients transplanted for acute liver disease have a higher early mortality but good long-term outcome. Patients transplanted because of liver tumour have a good initial outcome but survival continues to decline progressively (courtesy of Gerhard Opelz, Collaborative Transplant Study, L-75101-0211).

very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare much less well because of recurrent malignancy. Patients receiving a liver transplantation following hepatitis B or hepatitis C infection may develop graft failure as a result of recurrent viral disease. However, the availability of improved antiviral therapy has largely eliminated this problem in recipients with hepatitis B infection.

SMALL BOWEL TRANSPLANTATION

Progress in small bowel transplantation has lagged behind that of other types of organ transplantation but it is now a well-established therapy for highly selected recipients. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains very large amounts of lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and is made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain major problems after small bowel transplantation and the results obtained are inferior to those seen after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure to an extent that long-term parenteral nutrition is required. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. Conditions that may give rise to intestinal failure include the following:

- intestinal atresia;
- necrotising enterocolitis;
- volvulus;
- disorders of motility;
- mesenteric infarction;
- Crohn's disease;
- trauma;
- desmoids tumours.

Because of the substantial risks associated with small bowel transplantation, the procedure is only considered for those patients in whom long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5–1.0 patients per million of the population, and around 50 per cent of cases are children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver transplant or undertaken as a component of a multivisceral transplant. When possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a deceased donor comprises the entire small bowel, and may include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch) is anastomosed to the recipient aorta, and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the recipient jejunum or duodenum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an

end ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About one-half of all patients who require small bowel transplantation have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. Cholestatic liver disease due to TPN is especially common in children. When combined liver and small bowel transplantation is carried out, the two grafts are transplanted en bloc. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries and anastomosed to the recipient aorta. The portal vein anastomosis is as for isolated liver transplantation (Figure 81.31).

Multivisceral or 'cluster' transplants may be necessary in the case of large desmoid tumours when excision of both the small bowel and adjacent organs is required, when there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The one-year graft survival rate after small bowel transplantation is about 70 per cent for both isolated small bowel transplantation and for combined liver and small bowel transplantation. After three years, the graft survival rate is around 50 per cent. As already noted, however, patient survival is better after isolated small bowel transplantation than after combined liver and small bowel transplantation, when loss of the graft usually equates with death of the recipient. Most of the mortality after small bowel transplantation is due to sepsis and multiorgan failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression in order to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10 per cent) observed in patients who have undergone small bowel transplantation. Because of the large amount of donor lymphoid tissue transplanted, GVHD may be an added complication. Despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life free from the constraints of long-term nutritional support.

Figure 81.31 Combined liver and small bowel transplant in an adult shortly after reperfusion of the grafts. The small bowel is well perfused via the superior mesenteric artery anastomosed to the aorta on a patch along with the coeliac axis, and the venous blood drains into the portal vein via the superior mesenteric vein.

THORACIC ORGAN TRANSPLANTATION

Heart transplantation

Dr Christiaan Barnard performed the first human heart transplant in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Lower and Shumway in Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications for heart transplantation are ischaemic heart disease and idiopathic cardiomyopathy, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease that has failed to respond to all other conventional therapy and when predicted survival without transplantation is only 6–12 months. Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous, and measurement of pulmonary vascular resistance is mandatory because when it is raised the perioperative mortality is high.

Technique of heart transplantation

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 29°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then prepared and the left atrium is opened by making incisions (Figure 81.32) in the posterior wall, between the orifices of the pulmonary veins, to create an atrial cuff. The left and then right atrial

Figure 81.32 Recipient cardiectomy. After median sternotomy, the recipient is placed on cardiopulmonary bypass. Venous cannulae for bypass are sited in the superior vena cava (SVC) and inferior vena cava (IVC) via punctures in the right atrium (RA), and oxygenated blood is returned via a cannula in the ascending aorta (Ao). The diseased recipient heart is excised, leaving behind cuffs of right and left atria. PA, pulmonary artery; IPV/SPV, inferior/superior pulmonary veins; LA, left atrium (courtesy of J Dunning).

anastomoses are performed and the pulmonary and aortic arterial anastomoses are then completed (Figure 81.33). The patient is then rewarmed and weaned from cardiopulmonary bypass. Occasionally, heterotopic cardiac transplantation is undertaken, when the donor heart is placed adjacent to and augments the recipient's own heart.

Heart–lung, single-lung and double-lung transplantations

Pulmonary transplantation became a clinical reality when Dr Bruce Reitz performed the first successful combined heart–lung transplant in 1981. Combined heart–lung transplantation is still sometimes performed, usually in patients with pulmonary vascular disease in whom there is cardiac dysfunction due to congenital (e.g. Eisenmenger syndrome, in which the left-to-right shunt is reversed owing to pulmonary hypertension) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart–lung transplantation. Lung transplantation is more economical in terms of organ use, although if heart–lung transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation, the so-called ‘domino procedure’. Heart–lung transplantation is performed through a median sternotomy, taking particular care to avoid injury to the phrenic, vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart–lung block readied for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation are effective therapies for selected patients with end-stage chronic lung disease,

in whom declining lung function limits life expectancy despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension, emphysema and cystic fibrosis. Single-lung transplantation can be performed for pulmonary fibrosis. Single-lung transplantation is performed through a posterolateral thoracotomy and double-lung transplantation through a bilateral thoracotomy or median sternotomy. During lung transplantation, the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardiopulmonary bypass is usually required if pulmonary hypertension is present. Dehiscence of the airway anastomosis used to be common after heart–lung and lung transplantation, but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to <5 per cent. Late airway stenosis at the bronchial anastomosis due to ischaemia occurs in around 10 per cent of bronchial anastomoses and is treated by dilatation.

Outcome after thoracic organ transplantation

The one- and five-year graft survival rates after heart transplantation are around 85 and 70 per cent, respectively. The results after heart–lung and lung transplantation are less good, with one-year graft survival rates of around 75 per cent and five-year survival rates of around 50 per cent.

FUTURE PROSPECTS

The two major problems in organ transplantation are:

- 1 chronic graft rejection and the side effects of non-specific immunosuppression;
- 2 the shortage of organs for transplantation.

New immunosuppressive agents that have fewer or different agent-specific side effects than existing therapy are likely to enter clinical practice and there is continuing research into the development of non-invasive biomarkers (in urine or blood) that will allow early diagnosis of graft rejection. A long-standing goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance (Summary box 81.11). Transplantation tolerance would eliminate the need for long-term non-specific immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals with a variety of preconditioning regimens that often involve pretreatment schedules using donor bone marrow cells or donor antigen. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

Figure 81.33 Implantation of the donor heart. The donor left atrium is opened by an incision connecting the four pulmonary veins, excising the central portion. The left atrial anastomosis is performed, starting at the lateral wall of the donor and continuing inferiorly and superiorly, concluding with the interatrial septum. The right atrial anastomosis is performed matching the recipient atrium by an incision towards the donor right atrial appendage (dotted line), which avoids the sinus node at the cavoatrial junction. Finally, the pulmonary artery and aortic anastomosis are completed. Abbreviations as for Figure 81.32.

Summary box 81.11

Future developments in transplantation

- Novel immunosuppressive agents
- Non-invasive biomarkers for early diagnosis of graft rejection
- Donor-specific immunological tolerance
- Xenotransplantation
- Stem cell medicine and tissue engineering

The demand for human organs for transplantation is so great that deceased donors cannot ever satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have preformed antibodies directed against carbohydrate antigens expressed by pig organs, and these cause hyperacute rejection. The dominant carbohydrate antigen responsible is gal-1, 3- α gal. Progress has been made towards circumventing hyperacute xenograft rejection and pigs that have been genetically engineered not to express the gal-1, 3- α gal antigen have been produced. However, organs from genetically modified pigs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation, there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by porcine endogenous retrovirus (PERV). Lastly, there are unanswered questions regarding the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Finally, looking to the future, there is optimism that human pluripotent stem cells may ultimately provide a source of tissue transplants for treating a wide range of diseases. Attempts are now under way to define the cell signals needed to guide human embryonic and adult-induced pluripotent stem cells to differentiate *in vitro* into functional tissue of the desired cell type. These include insulin-producing cells, cardiac myocytes and neuronal tissue. Although cell transplantation is the initial goal, by combining the developments in stem cell medicine with those taking place in tissue engineering and biomaterials it may one day be possible to engineer more complex vascularised grafts for transplantation.

Common instruments used in general surgery

This is a list of some of the instruments used in open (as opposed to minimal access surgery) 'general surgery' with information on how they are used and about the people associated with them. It is hoped that this information will help the general surgical trainee answer questions on operative surgery in postgraduate examinations.

Langenbeck retractor. This small general purpose retractor is useful for holding open wounds, as in an open appendicectomy. They are often used in pairs (one in each of the assistant's hands). They stay in position best if the handles are lifted slightly so that the tips lock in under the fascia. The width of the lip of the retractors varies. Bernhard Rudolf Konrad von Langenbeck (1810–1887) was Professor of Surgery successively at Kiel and Berlin, Germany. He performed the first internal fixation of a femoral neck fracture in 1850.

Morris retractor. This is a big retractor which is useful for giving maximum exposure in large incisions such as those used in the abdomen. It can be used to improve visibility on one side of an incision (by pulling firmly in that direction); so is valuable during the initial phase of a laparotomy. Sir Henry Morris (1844–1926) was a surgeon at the Middlesex Hospital, London, UK.

Deaver retractor. This retractor is specifically designed for holding the liver up out of the way during a cholecystectomy. It needs to be used carefully to avoid damaging the liver. Some surgeons protect the liver with an abdominal pack before placing the blade on top. John Blair Deaver (1855–1931) was Professor of Surgery at the University of Pennsylvania Medical School, Philadelphia, PA, USA. He also described a paramedian incision for appendicectomy.

Dyball retractor. Used in major abdominal surgery to retract deeper parts of the abdominal wall or the bladder or the uterus while operating on the rectum and entering the rectovesical or rectouterine pouch. It has a lip at the bottom of the blade to prevent slippage. Care should be taken if it is used to retract the liver in operations in the region of the right upper quadrant as it may damage the liver parenchyma. Brennan Dyball was a distinguished West Country surgeon from Exeter. He also excelled as a carpenter and motor mechanic. He died in 1934 at the age of 62 leaving a great professional legacy to the Royal Devon and Exeter Hospital.

Joll retractor. This is a self-retaining retractor used in thyroid surgery. After making the collar incision and raising the lower and upper flaps fully, this retractor is then inserted. The two clips on the upper and lower edges are attached to the skin preferably with a swab over the skin edge. The central segment is then unscrewed to separate the two edges to obtain full exposure. Cecil Augustus Joll was a surgeon in London who first qualified as a dentist. He was regarded as 'a brilliant technician and an extraordinarily versatile surgeon' who operated on conditions 'from knees to necks and stomach to perineum'. A keen ornithologist, he was a connoisseur of all things good – furniture, pottery, food, wines and cigars. He died in 1945 at the age of 59.

Goligher retractor. This is a self-retaining retractor used in operations on the sigmoid colon and rectum, such as anterior resection and upper end of abdominoperineal resection. Once the abdomen has been opened and laparotomy performed, the patient is placed head down and all the small bowel is packed to the upper end of the abdomen. The retractor is then inserted with the side blades to separate the edges of the abdominal wall. The central blade is then inserted to keep the small bowel well tucked away from the operation site. All three blades come in different widths to fit in with the patient's build. John Cedric Goligher (1912–1998), Ulsterman by birth, Professor of Surgery at Leeds, his contributions to colorectal surgery in the world have been legendary. His operating theatres at Leeds General Infirmary 'have been the Mecca for surgeons from all over the world'. His book, *Surgery of the Anus, Rectum and Colon*, was regarded as the ultimate authority on the subject and had five editions.

St Mark's perineal retractor. This is used for the perineal part of an abdominoperineal resection. After making the perineal incision and adequate dissection of the perineal wound, the retractor is inserted. As the dissection proceeds, the retractor has to be repositioned. The pointed ends are directed towards the front. St Mark's Hospital, Harrow, UK, is recognised as a national and international referral centre for intestinal and colorectal disorders. It was founded in a small room in No. 11 Aldersgate Street. Established in 1854 on City Road in Hackney as St Mark's Hospital for Fistula and other Diseases of the Rectum. It was so named as it was opened on St Mark's Day, 25 April. In 1994, it moved to its present site in Harrow.

Travers retractor. This is a self-retaining retractor used for intermediate-type operations, such as herniorrhaphy, groin dissection for varicose veins and femoral embolectomy. It retracts skin and subcutaneous tissues; as the incision is deepened, the retractor has to be repositioned. If used incorrectly, it can traumatise the skin. For longer incisions, two such retractors may be used, one at each end of the incision for good exposure. Benjamin Travers (1783–1858) was a surgeon to the London Infirmary for Disease of the Eye (now Moorfields Ophthalmic Hospital). He is regarded as the first general hospital surgeon in England to devote himself specially to disease of the eye. He later became surgeon to St Thomas's Hospital and Vice-President and President of Royal College of Surgeons of England and a Fellow of the Royal Society. As an operator, he was regarded as clumsy and nervous. He had 'exquisite polish of manners, took off his hat and acknowledged salutes more elegantly than any contemporary dandy'.

West retractor. Used in a similar manner to the Travers retractor, this is ideal for minor procedures under local anaesthetic where the surgeon is operating without an assistant, e.g. lymph node biopsy, temporal artery biopsy. After making the incision and undermining the edges, the retractor is then inserted and the jaws are prised open gently. Charles Ernest West (1873–1951) 'aural surgeon' of St Bartholomew's Hospital is credited with devising this retractor. It is possible that he got the idea from Franz Weitlaner, an Austrian physician who published the first description of his retractor in the *Vienna Clinical Review* in 1905. He became known as 'the great spreader of surgery'. It would be safe to presume that the present retractor is West's modification of Weitlaner's spreader.

Czerny retractor. This is a double-ended retractor used to retract wound edges for intermediate-type procedures. One end has a blade with a lip which helps to retract without the edge slipping. The other end has two prongs and helps to retract the ends of an incision. When using it, a slight upward tilt gives a better exposure. It is used where a Langenbeck retractor can also be used, but the lip here is broader making it more versatile. Vincenz Czerny (1842–1915) was Professor of Surgery at Freiberg and Heidelberg in Germany. He was a disciple of Theodor Billroth. He was the originator of the concept of multidisciplinary management in cancer.

McIndoe scissors are used by surgeons to perform dissection respecting anatomical planes. The closed blades are inserted into a fascial plane, and then gently opened. The tissue to be divided can then be seen clearly and divided without risk of damage to vital structures. Sir Archibald Hector McIndoe (1900–1960) was a plastic surgeon at St Bartholomew's Hospital, London, and the Queen Victoria Hospital, East Grinstead, UK. He was born in New Zealand (cousin of Harold Gillies) and became a consultant plastic surgeon to the RAF during the Second World War. He supervised the rehabilitation of badly disfigured airmen who later formed the Guinea Pig Club.

DeBakey forceps allow the surgeon to grasp tissues firmly while minimising damage to the tissue held in the jaws of the forceps. They are useful for holding vessel walls in vascular surgery. Michael Ellis DeBakey (1908–2008) was Professor of Surgery at Baylor University College of Medicine, Houston, TX, USA. He was the first to successfully implant an artificial heart; he also performed the first successful carotid endarterectomy.

Gillies forceps have teeth and are ideal for holding tough tissues, such as skin. Sir Harold Gillies (1882–1960) was a plastic surgeon at St Bartholomew's Hospital, London, UK. He was born in New Zealand (cousin of Archibald McIndoe) and became one of the founders of British plastic surgery. He originated the tubed pedicle flap.

Adson forceps are non-toothed, and so are ideal for holding delicate tissues, such as bowel. Alfred Washington Adson (1887–1951) was Professor of Neurosurgery at the Mayo Clinic, Rochester, MN, USA. He was one of the first to use sympathectomy for the treatment of hypertension, and cervical sympathectomy for Raynaud's syndrome.

Allis forceps are used to hold soft tissues for a long period while minimising tissue damage. Using the ratchet they can be locked on to tissue, such as bowel, and can be used to provide gentle traction. Oscar Huntington Allis (1836–1921) was a surgeon at the Presbyterian Hospital, Philadelphia, PA, USA.

Babcock forceps. This is used to grasp any part of the bowel. The jaws are atraumatic and cause minimal tissue damage. Used commonly in appendectomy to grasp the appendix and deliver it out of the wound. Care is taken when using it not to perforate the inflamed appendix. William Wayne Babcock (1872–1963), Professor and Head of the Department of Surgery at the Temple University School of Medicine, Philadelphia for 40 years. 'He was the inventor of the acorn-shaped vein stripper, introduced the alloy steel wire sutures, wire mesh in hernia repairs, and zinc chloride in the treatment of osteomyelitic sinus'.

Spencer Wells forceps. These were one of the first ratchet forceps ever designed and are still very useful. They are often used in pairs for clamping an artery before dividing it. The cut ends of the artery are then tied off, and the forceps removed (carefully!). Sir Thomas Spencer Wells (1818–1897) was a surgeon at the Samaritan Free Hospital for Women and Children, London, UK. He was one of the earliest surgeons to make use of anaesthetics in operation.

Kocher dissector. This is used during a thyroidectomy to dissect the upper pole of the thyroid. The instrument is blunt and therefore the surgeon is highly unlikely to inadvertently damage the superior thyroid artery or the external laryngeal nerve. It is used to dissect the superior pedicle, the superior thyroid artery. Once it has been isolated, the dissector is pushed under the pedicle. A tie is then put through the eye of the dissector which at this stage doubles up as an aneurysm needle. The pedicle is thus tied three times as close to the gland as possible. With the dissector under the tied pedicle, a fine knife is now used to cut leaving two ties in the patient. The presence of the dissector under the pedicle prevents any damage to the underlying structures. Emil Theodor Kocher (1841–1917), Professor of Surgery at Berne, Switzerland, was awarded the Nobel Prize for Physiology or Medicine in 1909 for his work on the thyroid. The first surgeon to be a Nobel Laureate.

ACKNOWLEDGEMENTS

With thanks to Steven Kerr, Assistant Librarian, Royal College of Surgeons of Edinburgh.

Bailey & Love's Short Practice of Surgery remains one of the world's pre-eminent medical textbooks, beloved by generations of surgeons, with lifetime sales in excess of one million copies. Under the guidance of the eminent editors, the expert team of contributors have revised and updated the material throughout while retaining those features praised in previous editions.

The content is sub-divided into parts for ease of reference. Sections devoted to the underlying principles of surgical practice, investigation and diagnosis, and pre-operative care are followed by chapters covering all aspects of surgical trauma. The remainder of the book considers each of the surgical specialties in turn, from elective orthopaedics through skin, head and neck, breast and endocrine, cardiothoracic and vascular, abdominal and genitourinary to transplantation.

Key features:

- **Authoritative** – emphasises the importance of effective clinical examination and soundly based surgical principles while taking account throughout of the latest developments in surgical practice
- **Current** – text and illustrations fully revised with brand new chapters on patient safety, day care surgery and bariatric surgery
- **Readable** – preserves the clear, direct writing style, uncluttered by technical jargon, that has proved so popular in previous editions
- **User-friendly** – numerous photographs, explanatory line diagrams, learning objectives, summary boxes, biographical footnotes and memorable anecdotes support and enhance the textual descriptions

The 26th edition of **Bailey & Love** retains a wide appeal among all those studying surgery, from undergraduate medical students to those in preparation for their postgraduate surgical examinations. In addition, its high standing and reputation for unambiguous advice continue to make it the first point of reference for many practising surgeons.

About the editors:
